

Rheumatology

Rheumatology

VOLUME 1

MARC C. HOCHBERG, MD, MPH, MACP

Professor of Medicine and Epidemiology and Public Health
Head, Division of Rheumatology and Clinical Immunology
University of Maryland School of Medicine
Acting Director, Gerontology Research Education and Clinical Center
Veterans Affairs Maryland Health Care System
Baltimore, Maryland

ALAN J. SILMAN, MD, MSC, FRCP, FMEDSCI

Medical Director, Arthritis Research UK
Chesterfield, United Kingdom
Professor, Rheumatic Diseases Epidemiology
University of Manchester
Manchester, United Kingdom

JOSEF S. SMOLEN, MD, FRCP

Professor of Medicine
Chairman, Department of Medicine III
Division of Rheumatology
Medical University of Vienna
Chairman, Second Department of Medicine
Center for Rheumatic Diseases
Hietzing Hospital
Vienna, Austria

MICHAEL E. WEINBLATT, MD

John R. and Eileen K. Riedman Professor of Medicine
Harvard Medical School
R. Bruce and Joan M. Mickey Distinguished Chair in Rheumatology
Division of Rheumatology, Immunology, and Allergy
Brigham and Women's Hospital
Boston, Massachusetts

MICHAEL H. WEISMAN, MD

Cedars-Sinai Chair in Rheumatology
Director, Division of Rheumatology
Professor of Medicine
Cedars-Sinai Medical Center
Distinguished Professor of Medicine
David Geffen School of Medicine at University of California, Los Angeles
Los Angeles, California

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Engy Abdellatif, MBBCh, PhD

Specialist Registrar in Pathology
Salford Royal Hospitals National Health Service
Foundation Trust
Manchester, United Kingdom
Synovial fluid analysis

Aryeh M. Abeles, MD

Associate Clinical Professor
Rheumatology
University of Connecticut
Farmington, Connecticut
Inflammation and its mediators

Abby G. Abelson, MD

Chair, Department of Rheumatic and Immunologic
Diseases
Cleveland Clinic
Cleveland, Ohio
Management of osteoporosis

Abhishek Abhishek, MBBS, MD, MRCP(UK)

Rheumatology Consultant
Cambridge University Hospitals National Health
Service Trust
Cambridge, United Kingdom
Calcium pyrophosphate crystal-associated arthropathy

Steven B. Abramson, MD

Senior Vice President and Vice Dean for Education,
Faculty, and Academic Affairs
New York University Langone Medical Center
New York, New York
The microbiome in rheumatic diseases
Inflammation and its mediators

Jonathan D. Adachi, BSc, MD, FRCPC

Alliance for Better Bone Health Chair in
Rheumatology
Professor, Department of Medicine
Michael G. DeGroote School of Medicine
St Joseph's Healthcare
McMaster University
Hamilton, Ontario, Canada
Glucocorticoid-induced osteoporosis

Michael A. Adams, BSc, PhD

Professor of Biomechanics
Centre for Comparative and Clinical Anatomy
University of Bristol
Bristol, United Kingdom
Visiting Professor
Sir Run Run Shaw Hospital
Zhejiang University
Hangzhou, Zhejiang, China
Biomechanics of the spine

Thomas Aigner, MD

Head, Institute of Pathology
Medical Center Coburg
Coburg, Germany
Pathogenesis and pathology of osteoarthritis

Shizuo Akira, MD, PhD

Professor, Laboratory of Host Defense
Immunology Frontier Research Center
Osaka University
Suita City, Osaka, Japan
Principles of innate immunity

Daniel Aletaha, MD, MSc

Associate Professor
Department of Internal Medicine
Division of Rheumatology
Medical University of Vienna
Vienna, Austria
*Evaluation and outcomes of patients with rheumatoid
arthritis*

Antonios O. Aliprantis, MD, PhD

Assistant Professor
Department of Medicine
Division of Rheumatology
Brigham and Women's Hospital
Boston, Massachusetts
Relapsing polycondritis

Adriana Almeida de Jesus, MD, PhD

Postdoctoral Fellow
National Institute of Arthritis Musculoskeletal and
Skin Diseases
National Institutes of Health
Bethesda, Maryland
Monogenic autoinflammatory diseases

Roy D. Altman, MD

Professor
Medicine/Rheumatology and Immunology
University of California, Los Angeles
Los Angeles, California
Professor Emeritiis
Medicine/Rheumatology and Immunology
University of Miami
Miami, California
Clinical features of osteoarthritis
Management of osteoarthritis

Mary-Carmen Amigo, MD, FACP

Professor and Head
Rheumatology Service
ABC Medical Center
Mexico City, Mexico
*Antiphospholipid syndrome: overview of pathogenesis,
diagnosis, and management*

Martin Aringer, MD

Professor of Medicine
Division of Rheumatology
University Clinical Center Carl Gustav Carus at the
Technische Universität Dresden
Dresden, Germany
Signal transduction in immune cells

Dana P. Ascherman, MD

Associate Professor of Medicine
Medicine/Rheumatology
University of Miami Miller School of Medicine
Miami, Florida
*Clinical features, classification, and epidemiology of
inflammatory muscle disease*

Shervin Assassi, MD, MS

Associate Professor
Internal Medicine/Rheumatology
The University of Texas Medical School at Houston
Houston, Texas
Classification and epidemiology of scleroderma

Sergei P. Atamas, MD, PhD

Associate Professor
Department of Medicine
University of Maryland School of Medicine
Research Health Scientist
Research Service
Baltimore Veterans Affairs Medical Center
Baltimore, Maryland
Principles of adaptive immunity

Pedro Ming Azevedo, Sr., MD, PhD

Assistant Professor, Rheumatology
Faculdade de Medicina Evangelica do Parana
Curitiba, Brazil
Postdoctoral Fellow
The University of Auckland
Auckland, New Zealand
Department of Rheumatology and Immunology
Hospital Israelita Albert Einstein
Sao Paulo, Brazil
Acute rheumatic fever

Alan N. Baer, MD, FACP

Associate Professor of Medicine
Medicine (Rheumatology)
Johns Hopkins University
Director
Jerome L. Greene Sjögren's Syndrome Center
Clinical Director
Johns Hopkins Rheumatology
Good Samaritan Hospital
Baltimore, Maryland
Sjögren syndrome

Dominique Baeten, MD, PhD

Professor of Rheumatology
Clinical Immunology and Rheumatology
Academic Medical Center/University of Amsterdam
Amsterdam, The Netherlands
*Etiology, pathogenesis, and pathophysiology of
ankylosing spondylitis*

Colin Baines, MbChB

Specialist in Vascular and General Medicine
National Health Service Cross Hospital
University of Dundee
Dundee, United Kingdom
Raynaud phenomenon

Nancy A. Baker, ScD, MPH, OTR/L

Associate Professor
Occupational Therapy
University of Pittsburgh
Pittsburgh, Pennsylvania
*Principles of rehabilitation: physical and occupational
therapy*

Emese Balogh

Department of Rheumatology, Institute of Medicine
University of Debrecen Medical and Health
Sciences Center
Debrecen, Hungary
Angiogenesis and vasculogenesis in rheumatoid arthritis

Alejandro Balsa, MD, PhD

Staff Physician
Rheumatology Unit
Hospital Universitario La Paz
Rheumatology Associate Professor
Department of Medicine
Universidad Autonoma
Madrid, Spain
Infectious arthritis I: bacterial arthritis

Xenofon Baraliakos, MD

Associate Faculty Member
Rheumazentrum Ruhrgebiet
Herne, Germany
Imaging in spondylarthritis

Thomas Bardin, MD

Professor
Rheumatology
Université Paris VII
Head, Department of Rheumatology
Hôpital Lariboisière
Paris, France
Miscellaneous arthropathies

Les Barnsley, PhD, FRACP, FAFRM(RACP)

Head, Department of Rheumatology
Concord Hospital
Concord
Associate Professor
Department of Medicine
Sydney University
Sydney, New South Wales, Australia
Neck pain

Joan M. Bathon, MD

Professor of Medicine
Department of Medicine, Division of Rheumatology
Columbia University College of Physicians and Surgeons
New York, New York
Management of rheumatoid arthritis: synovitis

Angela Bauch, PhD

Senior Scientist
Research Center for Molecular Medicine of the
Austrian Academy of Sciences
Vienna, Austria
Systems biology

Jill J.F. Belch, MBChB, MD (Hon), FRCP, FRS

Professor of Vascular Medicine and Tayside
Research and Development Director
Division of Cardiovascular and Diabetes Medicine
University of Dundee School of Medicine
Dundee, United Kingdom
Founder Fellow
Academy of Medical Sciences London
London, United Kingdom
Raynaud phenomenon

Nicholas Bellamy, MD, MBChB, MSc, DSc

Professor
The University of Queensland School of Medicine
Royal Brisbane and Women's Hospital
Herston, Queensland, Australia
Principles of clinical outcome assessment

Teresita Bellido, PhD

Professor, Anatomy and Cell Biology
Professor, Internal Medicine Division of
Endocrinology
Indiana University School of Medicine
Indianapolis, Indiana
Bone structure and function

Michael Benjamin, BSc, PhD

Professor Emeritus
School of Biosciences
Cardiff University
Cardiff, United Kingdom
Enthesopathies

Michael W. Beresford, MBChB, PhD

Professor in Child Health
Department of Women's and Children's Health
Institute of Translational Medicine
University of Liverpool
Honorary Consultant Paediatric Rheumatologist
Clinical Academic Department of Paediatric
Rheumatology
Alder Hey Children's National Health Service
Foundation Trust
Liverpool, United Kingdom
Connective tissues diseases in children

Brian Berman, MD

Professor and Director
Center for Integrative Medicine
University of Maryland
Baltimore, Maryland
Complementary and alternative medicine

Bonnie Lee Bermas, MD

Director, Lupus Center
Division of Rheumatology
Brigham and Women's Hospital
Assistant Professor of Medicine
Harvard Medical School
Boston, Massachusetts
Drugs and pregnancy

George Bertias, MD, PhD

Lecturer
Rheumatology, Clinical Immunology, and Allergy
University of Crete
Institute of Molecular Biology and Biotechnology
Foundation of Research and Technology
Iraklion, Greece
Systemic lupus erythematosus: treatment—renal involvement

John P. Bilezikian, MD

Dorothy L. and Daniel H. Silberberg Professor of
Medicine and Professor of Pharmacology
Department of Medicine
Columbia University
New York, New York
Primary hyperparathyroidism: rheumatologic manifestations and bone disease

Yelda Bilginer, MD, MSc

Associate Professor
Pediatric Nephrology and Rheumatology
Hacettepe University
Ankara, Turkey
Henoch-Schönlein purpura/immunoglobulin-A vasculitis

Julius Birnbaum, MD

Assistant Professor
Departments of Medicine and Neurology
Johns Hopkins Hospital
Baltimore, Maryland
The nervous system in rheumatic disease

Felicity L. Bishop, MSc, PhD

Psychology
University of Southampton
Southampton, United Kingdom
Complementary and alternative medicine

Jane F. Bleasel, MBBS, PhD, FRACP

Clinical Associate Professor
Department of Rheumatology
Royal Prince Alfred Hospital Institute of
Rheumatology and Orthopaedics
University of Sydney
Camperdown, New South Wales, Australia
Hemophilia and von Willebrand disease

Markus Böhm, MD

Professor, Department of Dermatology
University of Münster
Münster, Germany
Skin in rheumatic disease

Marcy B. Bolster, MD

Associate Professor of Medicine
Harvard Medical School
Division of Rheumatology
Massachusetts General Hospital
Boston, Massachusetts
Clinical features of systemic sclerosis

Stefano Bombardieri, MD

Professor of Rheumatology
Director, Specialty School of Rheumatology
University of Pisa
Director, Rheumatology Operative Unit
Director, Department of Internal Medicine
Azienda Ospedaliera Universitaria Pisana
Pisa, Italy
Cryoglobulinemia

Michael Bonelli, MD

Molecular Immunology and Inflammation Branch
National Institute of Arthritis and Musculoskeletal
and Skin Diseases
National Institutes of Health
Bethesda, Maryland
Signal transduction in immune cells

Sydney L. Bonnick, MD, FACP

Medical Director
Clinical Research Center of North Texas
Adjunct Professor
Department of Kinesiology and Biological Sciences
University of North Texas
Denton, Texas
Dual x-ray absorptiometry and measurement of bone

Dimitrios T. Boumpas, MD, FACP

Professor, Department of Medicine
National and Kapodistrian University of Athens
Medical School
Affiliated Investigator
Immunobiology Center
Biomedical Research Foundation of the Academy of
Athens
Athens, Greece
Affiliated Investigator
Infection and Immunity Branch
Institute of Molecular Biology and Biotechnology
Iraklion, Greece
Systemic lupus erythematosus: treatment—renal involvement

Aline Bozec, PhD

Professor of Rheumatology and Immunology
Department of Internal Medicine 3
University of Erlangen–Nuremberg Faculty of
Medicine
Erlangen, Germany
Osteoimmunology

Richard D. Brasington, Jr., MD

Professor of Medicine
Division of Rheumatology
Washington University in St Louis
St. Louis, Missouri
Clinical features of rheumatoid arthritis

Juergen Braun, MD

Professor and Medical Director
Rheumazentrum Ruhrgebiet
Herne, Germany
Imaging in spondyloarthritis

Matthew A. Brown, MD, FRACP

Professor of Immunogenetics
Princess Alexandra Hospital
University of Queensland Diamantina Institute
Translational Research Institute
Brisbane, Queensland, Australia
Genetics of axial spondyloarthritis

Ian N. Bruce, MD, FRCP

Professor of Rheumatology
Arthritis Research UK Centre of Excellence in
Epidemiology
Centre for Musculoskeletal Research
Institute of Inflammation and Repair
The University of Manchester
Manchester, United Kingdom
Clinical features of psoriatic arthritis

William D. Bugbee, MD

Attending Physician
Division of Orthopaedic Surgery
Scripps Clinic
La Jolla, California
Professor
Orthopaedic Surgery
University of California, San Diego
San Diego, California
The hip

Marwan A.S. Bukhari, MBBS, MSc, FRCP, PhD

Consultant Rheumatologist
Department of Rheumatology
Royal Lancaster Infirmary
Lancaster, United Kingdom
Clinical Sciences
University of Liverpool
Liverpool, United Kingdom
Mucopolysaccharidoses

Rubén Burgos-Vargas, MD

Investigator in Medical Sciences
Department of Rheumatology
Hospital General de México
Professor of Medicine
School of Medicine
Universidad Nacional Autonoma de Mexico
Mexico City, Mexico
Juvenile-onset spondyloarthritis

Gerd-Rüdiger Burmester, PhD, MD

Professor of Medicine
Rheumatology and Clinical Immunology
Charité-Universitätsmedizin Berlin
Berlin, Germany
Role of laboratory tests in rheumatic disorders

Jane C. Burns, MD

Professor and Director
Kawasaki Disease Research Center
Department of Pediatrics
University of California, San Diego School of
Medicine
La Jolla, California
Kawasaki disease

David B. Burr, PhD, FAAA

Distinguished Professor
Anatomy and Cell Biology
Indiana University School of Medicine
Associate Vice Chancellor for Research
Indiana University-Purdue University
Indianapolis, Indiana
Bone structure and function

Frank Buttgereit, MD

Professor
Department of Rheumatology and Clinical
Immunology
Charité University Medicine Berlin
Berlin, Germany
Systemic glucocorticoids in rheumatology

Vivian P. Bykerk, MD

Assistant Professor of Medicine
Department of Medicine
Hospital for Special Surgery
New York, New York
*Nonimmunosuppressive disease-modifying
antirheumatic drugs*

Leonard H. Calabrese, DO

Professor of Medicine
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University
Vice Chairman
Department of Rheumatic and Immunologic
Diseases
R.J. Fasenmyer Chair of Clinical Immunology
Theodore F. Classen DO Chair of Osteopathic
Research and Education
Cleveland Clinic Foundation
Cleveland, Ohio
Rheumatologic aspects of viral infections

Jeffrey P. Callen, MD

Professor of Medicine (Dermatology)
Chief, Division of Dermatology
University of Louisville
Louisville, Kentucky
Cutaneous vasculitis and panniculitis

Sabrina Cavallo, MSc, BSc (OT)

Ecole de Santé Publique
Université de Montréal
Occupational Therapist
Department of Occupational Therapy
Montreal Children's Hospital of the McGill
University Health Centre
Montréal, Québec, Canada
*Rehabilitation and psychosocial issues in juvenile
idiopathic arthritis*

Tim E. Cawston, BSc, PhD

William Leech Professor of Rheumatology
School of Clinical Medical Sciences
Musculoskeletal Research Group
Institute of Cellular Medicine
Newcastle University
Newcastle upon Tyne, United Kingdom
Tissue destruction and repair

Vinod Chandran, MBBS, MD, DM, PhD

Assistant Professor
Division of Rheumatology
Department of Medicine
University of Toronto
Co-Director, Psoriatic Arthritis Program
Centre for Prognosis Studies in the Rheumatic
Diseases
Toronto Western Hospital
University Health Network
Toronto, Ontario, Canada
Management of psoriatic arthritis

Michael Denis Chard, MD, FRCP

Consultant Rheumatologist
Worthing Hospital
Worthing, West Sussex, United Kingdom
The elbow

Prateek Chaudhary, DO, MPH

Rheumatology Fellow
Department of Rheumatology
Duke University Medical Center
Durham, North Carolina
*Systemic lupus erythematosus in the pregnant patient
and neonatal lupus*

Lan X. Chen, MD, PhD

Attending Physician
Department of Medicine
Penn Presbyterian Medical Center
Philadelphia, Pennsylvania
Other crystal-related arthropathies

Hyon K. Choi, MD, PhD

Professor of Medicine
Section of Rheumatology
Clinical Epidemiology Unit
Boston University School of Medicine
Boston, Massachusetts
Epidemiology of gout

Ernest H. Choy, MD, FRCP

Professor and Head
Rheumatology and Translational Research
Institute of Infection and Immunity
Director, Arthritis Research UK Cardiff Regional
Experimental Arthritis Treatment and
Evaluation Centre
Cardiff University School of Medicine
Cardiff, United Kingdom
T-cell costimulation and other directed therapies

Lisa Christopher-Stine, MD, MPH

Co-Director, Johns Hopkins Myositis Center
Assistant Professor of Medicine and Neurology
Division of Rheumatology
Johns Hopkins University
Baltimore, Maryland
*Metabolic, drug-induced, and other noninflammatory
myopathies*

Alvina D. Chu, MD

Adjunct Clinical Instructor
Division of Immunology and Rheumatology
Stanford University School of Medicine
Palo Alto, California
*Assessing disease activity and outcome in systemic
lupus erythematosus*

Daniel J. Clauw, MD

Professor
Anesthesiology and Medicine (Rheumatology)
University of Michigan
Ann Arbor, Michigan
Fibromyalgia and related syndromes

Philip J. Clements, MD, MPH

Emeritus Professor of Medicine/Rheumatology
David Geffen School of Medicine at the University
of California, Los Angeles
Los Angeles, California
*Immunosuppressives: cyclosporine, cyclophosphamide,
azathioprine, mycophenolate mofetil*

Megan E.B. Clowse, MD, MPH

Assistant Professor
Medicine
Duke University Medical Center
Durham, North Carolina
Systemic lupus erythematosus in the pregnant patient and neonatal lupus

J. Gerry Coghlan, MD, FRCP

Department of Cardiology
Royal Free Hospital
London, United Kingdom
The heart in rheumatic disease

Philip G. Conaghan, MBBS, PhD, FRACP, FRCP

Professor of Musculoskeletal Medicine
Leeds Institute of Rheumatic and Musculoskeletal Medicine
University of Leeds
Deputy Director
Leeds Musculoskeletal Biomedical Research Unit
National Institutes of Health Research
Leeds, United Kingdom
Imaging of osteoarthritis

Cyrus Cooper, FMedSci

Professor of Rheumatology and Director
Medical Research Council Lifecourse
Epidemiology Unit
University of Southampton
Southampton, United Kingdom
Epidemiology and classification of osteoporosis

Karen H. Costenbader, MD, MPH

Co-Director, Lupus Center
Division of Rheumatology, Immunology, and Allergy
Brigham and Women's Hospital
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts
Epidemiology and classification of systemic lupus erythematosus

Paul Creamer, MD, FRCP

Physician
Department of Rheumatology
North Bristol Trust
Bristol, United Kingdom
Neuropathic arthropathy

José C. Crispín, MD

Assistant Professor of Medicine
Department of Medicine
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts
Pathogenesis of lupus

Bruce N. Cronstein, MD

Paul R. Esserman Professor of Medicine
New York University School of Medicine
New York, New York
Pharmacogenomics in rheumatology

Raymond Cross, MD

Associate Professor of Medicine
Division of Gastroenterology and Hepatology
Director, Inflammatory Bowel Disease Program
University of Maryland School of Medicine
Chief, Gastrointestinal Section
Veterans Affairs Maryland Health Care System
Baltimore, Maryland
Gastrointestinal tract and rheumatic disease

Natalie E. Cusano, MD

Assistant Professor of Medicine
Department of Medicine
Columbia University College of Physicians and Surgeons
New York, New York
Primary hyperparathyroidism: rheumatologic manifestations and bone disease

Maurizio Cutolo, MD

Professor, Rheumatology and Internal Medicine
Director, Research Laboratories and Academic
Division of Clinical Rheumatology
Director, Postgraduate Academic School of Rheumatology
University of Genoa
Genoa, Italy
Effects of the neuroendocrine system on development and function of the immune system

Chris D'Adamo, PhD

Director of Research
Center for Integrative Medicine
Assistant Professor
Department of Family and Community Medicine
Assistant Professor
Department of Epidemiology and Public Health
University of Maryland School of Medicine
Baltimore, Maryland
Complementary and alternative medicine

Vivette D'Agati, MD

Professor of Pathology
Department of Pathology
Columbia University College of Physicians and Surgeons
Director, Renal Pathology Laboratory
Department of Pathology
Columbia University Medical Center
New York, New York
Immunopathology of systemic lupus erythematosus

David P. D'Cruz, MD, FRCP

Consultant Rheumatologist
The Louise Coote Lupus Unit
St Thomas' Hospital
London, United Kingdom
The heart in rheumatic disease

Hanne Dagfinrud, PhD

Associate Professor
University of Oslo Faculty of Medicine
Senior Researcher
National Resource Center for Rehabilitation in Rheumatology
Diakonhjemmet Hospital
Oslo, Norway
Multidisciplinary approach to rheumatoid arthritis

David I. Daikh, MD, PhD

Associate Professor of Medicine
Kenneth H. Fye Chair in Rheumatology
University of California, San Francisco
Chief, Rheumatology Section
Department of Medicine
San Francisco Veterans Affairs Medical Center
San Francisco, California
Animal models of lupus

Nicola Dalbeth, MD, MBChB, FRACP

Associate Professor and Rheumatologist
Department of Medicine
University of Auckland
Auckland, New Zealand
Etiology and pathogenesis of gout

Seamus E. Dalton, MBBS, FACSP, FACRM, FAFRM(RACP)

Consultant, Rehabilitation and Sports Medicine
North Sydney Orthopaedic and Sports Medicine Centre
Sydney, New South Wales, Australia
The shoulder

Shouvik Dass, MB BChir, MRCP(UK)

Honorary Senior Lecturer
Leeds Institute of Rheumatic and Musculoskeletal Medicine
University of Leeds
Consultant Rheumatologist
Department of Rheumatology
Leeds Teaching Hospitals National Health Service Trust
Leeds, United Kingdom
B-cell depletion

Aileen M. Davis, BScPT, MSc, PhD

Senior Scientist
Division of Health Care and Outcomes
Toronto Western Research Institute
Professor
Institute of Health Policy, Management, and Evaluation
Professor, Department of Physical Therapy and Graduate Department of Rehabilitation Science
University of Toronto
Interim Director, Toronto Musculoskeletal Centre
Toronto, Ontario, Canada
Assessment of the patient with osteoarthritis and measurement of outcomes

Karel De Ceulaer, MD

Consultant Rheumatologist
Department of Medicine
University of the West Indies
Kingston, Jamaica
Joint and bone lesions in hemoglobinopathies

Chad L. Deal, MD

Associate Professor of Medicine
Head, Center for Osteoporosis and Metabolic Bone Disease
Vice Chair, Quality and Outcomes
Department of Rheumatology
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University
Cleveland, Ohio
Management of osteoporosis

Kevin D. Deane, MD, PhD

Associate Professor of Medicine
Division of Rheumatology
University of Colorado School of Medicine
Aurora, Colorado
Preclinical features of rheumatoid arthritis

Alessandra Della Rossa, MD

Medical Director
Musculoskeletal and Skin Disorders
Rheumatology Unit
Pisa, Italy
Cryoglobulinemia

Paul F. Dellaripa, MD

Associate Professor
Division of Rheumatology, Immunology, and Allergy
Department of Medicine
Brigham and Women's Hospital
Boston, Massachusetts
The lung in rheumatic disease

Elaine Dennison, MB BChir, MSc, FRCP, PhD

Professor of Musculoskeletal Epidemiology
Medical Research Council Lifecourse
Epidemiology Unit
Southampton University
Southampton, United Kingdom
Professor of Clinical Research
School of Biological Sciences
Victoria University
Wellington, New Zealand
Epidemiology and classification of osteoporosis

Christopher P. Denton, PhD, FRCP

Professor of Experimental Rheumatology
Centre for Rheumatology
University College London
Consultant Rheumatologist
Centre for Rheumatology
Royal Free Hospital
London, United Kingdom
Pulmonary management of systemic sclerosis

Paul Dieppe, BSc, MD, FRCP, FFPH

Professor of Health and Wellbeing
University of Exeter Medical School
Exeter, United Kingdom
Placebos, caring, and healing in rheumatology

Michael Doherty, MD, FRCP

Professor of Rheumatology
Academic Rheumatology
University of Nottingham
Nottingham, United Kingdom
Calcium pyrophosphate crystal-associated arthropathy

Patricia Dolan, BSc, PhD

Reader in Biomechanics
Centre for Comparative and Clinical Anatomy
University of Bristol
Bristol, United Kingdom
Visiting Professor
Sir Run Run Shaw Hospital
Zhejiang University
Hangzhou, Zhejiang, China
Biomechanics of the spine

Rachelle Donn, MB ChB, PhD

Reader in Complex Disease Genetics
Musculoskeletal Research Group
Arthritis Research UK
University of Manchester
Manchester, United Kingdom
Etiology and pathogenesis of juvenile idiopathic arthritis

Olga Dvorkina, MD

Clinical Assistant Professor
Department of Medicine
State University of New York Downstate Medical
Center
Brooklyn, New York
Clinical features of systemic lupus erythematosus

George S.M. Dyer, MD, FACS

Assistant Professor of Orthopaedic Surgery
Program Director, Harvard Combined Orthopaedic
Residency
Harvard Medical School
Surgeon, Orthopaedic Upper Extremity
Department of Orthopaedic Surgery
Brigham and Women's Hospital
Boston, Massachusetts
The wrist and hand

Richard Eastell, MD, FRCP, FRCPATH, FMedSci

Professor, Bone Metabolism
Human Metabolism
University of Sheffield
Sheffield, United Kingdom
Biochemical markers in bone disease

N. Lawrence Edwards, MD, FACP, FACR

Professor and Program Director
Vice Chairman, Department of Medicine
University of Florida
Chief, Section of Rheumatology
Medical Service
Malcom Randall Veterans Affairs Medical Center
Gainesville, Florida
Clinical gout

Paul Emery, MD, FRCP

Arthritis Research United Kingdom Professor of
Rheumatology
Director, Leeds Institute of Rheumatic and
Musculoskeletal Medicine
University of Leeds
Director
National Institute for Health Research
Leeds Musculoskeletal Biomedical Research Unit
Leeds Teaching Hospital National Health Service
Trust
Leeds, United Kingdom
B-cell depletion

Gurhan Erturan, MBBS, MRCS

Orthopaedic Registrar
Nuffield Orthopaedic Centre
Oxford, United Kingdom
The knee

Luis R. Espinoza, MD

Professor and Chief
Internal Medicine
Louisiana State University Health Science Center
New Orleans, Louisiana
*Infectious arthritis II: mycobacterial, brucellar, fungal,
and parasitic arthritis*

Steve Eyre, PhD

Research Associate
Arthritis Research UK Epidemiology Unit
University of Manchester
Manchester, United Kingdom
Principles of genetic epidemiology

Antonios C. Fanouriakis, MD

Rheumatology Fellow
Rheumatology, Clinical Immunology, and Allergy
University Hospital of Crete
Heraklion, Crete, Greece
*Systemic lupus erythematosus: treatment—renal
involvement*

Joshua Farber, MD

Senior Investigator
Laboratory of Molecular Immunology, Division of
Intramural Research
National Institute of Arthritis and Musculoskeletal
and Skin Diseases
National Institutes of Health
Bethesda, Maryland
Cytokines

Shawn Farrokhi, PhD, DPT

Assistant Professor
Departments of Physical Therapy and
Bioengineering
Co-Director, Human Movements Research
Laboratory
University of Pittsburgh
Pittsburgh, Pennsylvania
*Principles of rehabilitation: physical and occupational
therapy*

Anders Fasth, MD, PhD

Professor
Department of Pediatrics
University of Gothenburg
Professor
Department of Pediatric Immunology
The Queen Silvia Children's Hospital
Gothenburg, Sweden
Senior Consultant
Servicio de Inmunología y Reumatología Pediátrica,
Hospital Nacional de
Niños "Dr. Carlos Sáenz Herrera"
San José, Costa Rica
Clinical features of juvenile idiopathic arthritis

Eugen Feist, MD

Associate Professor of Medicine
Rheumatology and Clinical Immunology
Charité-Universitätsmedizin Berlin
Berlin, Germany
Role of laboratory tests in rheumatic disorders

Debbie Feldman, BScPT, MSc, PhD

Professor, Faculty of Medicine
School of Rehabilitation
Université de Montréal
Montréal, Quebec, Canada
*Rehabilitation and psychosocial issues in juvenile
idiopathic arthritis*

David T. Felson, MD, MPH

Professor of Medicine and Epidemiology
Medicine
Boston University School of Medicine
Boston, Massachusetts
Professor of Medicine and Public Health
University of Manchester
Manchester, United Kingdom
*Local and systemic risk factors for incidence and
progression of osteoarthritis*

John D. Fisk, PhD

Psychologist
Queen Elizabeth II Health Sciences Centre
Associate Professor, Department of Psychiatry
Assistant Professor, Department of Medicine
Adjunct Professor, Department of Psychology
Dalhousie University
Halifax, Nova Scotia, Canada
Treatment of neuropsychiatric lupus

G. Kelley Fitzgerald, PhD, FAPTA

Professor
Department of Physical Therapy
School of Health and Rehabilitation Sciences
Director
Physical Therapy Clinical and Translational
Research Center
University of Pittsburgh
Pittsburgh, Pennsylvania
*Principles of rehabilitation: physical and occupational
therapy*

Raymond H. Flores, MD

Associate Professor of Medicine
Division of Rheumatology and Clinical Immunology
University of Maryland School of Medicine
Baltimore, Maryland
Entrapment neuropathies and compartment syndromes

David A. Fox, MD

Professor
Division of Rheumatology
University of Michigan
Ann Arbor, Michigan
Emerging therapeutic targets: GM-CSF, IL-17, and IL-23

Clair A. Francomano, MD

Associate Professor of Medicine
Johns Hopkins University School of Medicine
Director, Adult Genetics
Harvey Institute for Human Genetics
Greater Baltimore Medical Center
Baltimore, Maryland
Skeletal dysplasias

Jennifer Frangos, DDS

Resident, Oral and Maxillofacial Surgery
University of Maryland Medical Center
Baltimore, Maryland
The temporomandibular joint

Anthony J. Freemont, BSc, MBBS, FRCP, FRCPath

Proctor Professor of Pathology
Head, Undergraduate Medical Education
Manchester Medical School
University of Manchester
Manchester, United Kingdom
Synovial fluid analysis

Kevin B. Fricka, MD

Clinical Instructor
Anderson Orthopaedic Adult Reconstructive Hip and Knee Fellowship
Anderson Orthopaedic Clinic
Alexandria, Virginia
The hip

Daniel E. Furst, MD

Carl M. Pearson Professor of Rheumatology
Division of Rheumatology
Department of Medicine
David Geffen School of Medicine at the University of California, Los Angeles
Director of Therapeutic Research
Department of Medicine
Ronald Reagan Hospital
Los Angeles, California
Immunosuppressives: cyclosporine, cyclophosphamide, azathioprine, mycophenolate mofetil

Cem Gabay, MD

Professor of Medicine
Head, Division of Rheumatology
University Hospitals of Geneva
Geneva, Switzerland
Cytokine neutralizers: interleukin-1 inhibitors

Massimo Gadina, PhD

Translational Immunology Section
Director, Office of Science and Technology
National Institute of Arthritis and Musculoskeletal and Skin Diseases
National Institutes of Health
Bethesda, Maryland
Cytokines

J.S. Hill Gaston, PhD, BM, BCh, FRCP, FMedSci

Professor of Rheumatology
University of Cambridge
Cambridge, United Kingdom
Cellular immunity in rheumatoid arthritis

Steffen Gay, MD

Professor of Experimental Rheumatology
Department of Rheumatology
University Hospital
Zurich, Switzerland
Epigenetics in rheumatology

Lianne S. Gensler, MD

Assistant Clinical Professor of Medicine
Director, Spondylitis Clinic
Department of Medicine
University of California, San Francisco
San Francisco, California
Clinical features of axial spondyloarthritis

Laura Geraldino-Pardilla, MD, MSc

Assistant Professor in Clinical Medicine
Division of Rheumatology
Columbia University College of Physicians and Surgeons
New York-Presbyterian Hospital
New York, New York
Management of rheumatoid arthritis: synovitis

Danielle M. Gerlag, MD, PhD

Rheumatology Internist
Clinical Research Team Leader
Clinical Immunology and Rheumatology
Academic Medical Center
University of Amsterdam
Amsterdam, Noord-Holland, The Netherlands
Minimally invasive procedures

Ellen M. Ginzler, MD, PhD

Distinguished Teaching Professor
Chief of Rheumatology
Department of Medicine
Rheumatology Division
State University of New York Downstate Medical Center
Brooklyn, New York
Clinical features of systemic lupus erythematosus

Alison M. Gizinski, MD

Clinical Assistant Professor
Internal Medicine
Division of Rheumatology
University of Arkansas for Medical Sciences
Little Rock, Arkansas
Emerging therapeutic targets: GM-CSF, IL-17, and IL-23

Dafna D. Gladman, MD, FRCPC

Professor, Department of Medicine
University of Toronto
Senior Scientist
Toronto Western Research Institute
Director, Psoriatic Arthritis Program
University Health Network
Toronto, Ontario, Canada
Management of psoriatic arthritis

Garry E. Gold, MD

Professor
Department of Radiology
Stanford University
Stanford, California
Functional magnetic resonance imaging

Raphaela Goldbach-Mansky, MD, MHS

Acting Chief, Translational Autoinflammatory Disease Section
National Institute of Arthritis and Musculoskeletal and Skin Diseases
National Institutes of Health
Bethesda, Maryland
Monogenic autoinflammatory diseases

Sarah Goldingay, PhD

Lecturer
College of Humanities
University of Exeter
Exeter, Devon, United Kingdom
Placebos, caring, and healing in rheumatology

Sharon M. Gordon, DDS, MPH, PhD

Professor
Department of Oral and Maxillofacial Surgery
University of Maryland School of Dentistry
Baltimore, Maryland
Professor and Chair
Department of Foundational Sciences
Associate Dean for Research
East Carolina University School of Dental Medicine
Greenville, North Carolina
The temporomandibular joint

Rachel Gorodkin, MBChB, PhD, FRCP

Consultant Rheumatologist
The Kellgren Centre for Rheumatology
Manchester Royal Infirmary
Honorary Lecturer
Faculty of Medical and Human Sciences
University of Manchester
Manchester, United Kingdom
Complex regional pain syndrome

Jörg J. Goronzy, MD, PhD

Professor of Medicine
Medicine, Immunology, and Rheumatology
Stanford University School of Medicine
Stanford, California
Polymyalgia rheumatica and giant cell arteritis

Simon Görtz, MD

Resident Physician
Department of Orthopaedic Surgery
University of California, San Diego
San Diego, California
The hip

Rodney Grahame, MD, FRCP, FACP

Honorary Consultant, Rheumatology
University College London Hospitals
Honorary Professor, Medicine
University College London
London, United Kingdom
Affiliate Professor
University of Washington School of Medicine
Seattle, Washington
Hypermobility syndrome

Andrew J. Grainger, BM BS, MRCP, FRCR

Consultant and Honorary Senior Lecturer
Musculoskeletal Radiology
Leeds Teaching Hospitals
Leeds, United Kingdom
Imaging of osteoarthritis

Ellen M. Gravallese, MD

Myles J. McDonough Chair in Rheumatology
Professor of Medicine and Cell and Developmental
Biology
University of Massachusetts Medical School
Chief, Division of Rheumatology
Department of Medicine
University of Massachusetts Memorial Medical
Center
Worcester, Massachusetts
The rheumatoid joint: synovitis and tissue destruction

Jeffrey D. Greenberg, MD, MPH

Assistant Professor of Medicine
Division of Rheumatology
New York University School of Medicine
New York, New York
Pharmacogenomics in rheumatology

Bansari Gujar, MBBS

Post-doctoral Fellow
Division of Rheumatology
University of Maryland
Baltimore, Maryland
Entrapment neuropathies and compartment syndromes

Matilda Hagan, MD

Fellow
Gastroenterology and Hepatology Division
University of Maryland School of Medicine
Baltimore, Maryland
Gastrointestinal tract and rheumatic disease

Karlene Hagley, MBBS, MD

Consultant in Internal Medicine
Department of Medicine
Spanish Town Hospital
St. Catherine, Jamaica
Associate Lecturer
Department of Medicine
University of the West Indies
Kingston, Jamaica
Joint and bone lesions in hemoglobinopathies

Alan J. Hakim, MB, FRCP

Consultant Rheumatologist and Acute Physician
Whipps Cross Hospital
BartsHealth National Health Service Trust
Honorary Senior Lecturer
Experimental Medicine
Queen Mary University London
London, United Kingdom
Hypermobility syndrome

John C. Hall, PhD

Assistant Professor
Department of Medicine
Division of Rheumatology
Johns Hopkins University School of Medicine
Baltimore, Maryland
Sjögren syndrome

Vedat Hamuryudan, MD

Professor
Department of Medicine
Division of Rheumatology
University of Istanbul
Cerrahpasa Medical Faculty
Istanbul, Turkey
Behçet syndrome

John G. Hanly, MD, FRCP(C)

Professor of Medicine and Pathology
Departments of Medicine and Pathology
Dalhousie University
Attending Staff Rheumatologist
Division of Rheumatology
Capital Health
Halifax, Nova Scotia, Canada
Treatment of neuropsychiatric lupus

Eric P. Hanson, MD

Immunoregulation Section
Autoimmunity Branch
National Institute of Arthritis, Musculoskeletal, and
Skin Disease
National Institutes of Health
Bethesda, Maryland
Signal transduction in immune cells

Boulos Haraoui, MD, FRCPC

Associate Professor of Medicine
Department of Medicine
Université de Montréal
Montreal, Quebec, Canada
Leflunomide

John B. Harley, MD, PhD

Professor and Director
Division of Rheumatology and The Center for
Autoimmune Genomics and Etiology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio
Genetics of lupus

Philip J. Hashkes, MD, MSc

Head, Pediatric Rheumatology Unit
Department of Pediatrics
Shaare Zedek Medical Center
Clinical Associate Professor of Pediatrics
Hebrew University Hadassah School of Medicine
Jerusalem, Israel
Associate Professor of Medicine and Pediatrics
Cleveland Clinic Lerner School of Medicine of Case
Western Reserve University
Cleveland, Ohio
Management of juvenile idiopathic arthritis

Gillian A. Hawker, MD, MSc

Professor
Medicine/Rheumatology
University of Toronto
Chief of Medicine
Medicine/Rheumatology
Women's College Hospital
Toronto, Ontario, Canada
*Assessment of the patient with osteoarthritis and
measurement of outcomes*

Philip N. Hawkins, PhD, FRCP, FRCPath, FMedSci

Professor
National Amyloidosis Centre
University College London Royal Free Hospital
London, United Kingdom
Amyloidosis

Turid Heiberg

Research Leader/Associate Professor
Department of Research, Innovation, and Education
Oslo University Hospital/Lovisenberg Diaconal
University College
Oslo, Norway
Multidisciplinary approach to rheumatoid arthritis

†Dick Heinegård, MD, PhD

Professor
Department of Clinical Sciences
Division of Rheumatology–Molecular Skeletal
Biology
Lund University
Lund, Sweden
Articular cartilage

Simon M. Helfgott, MD, CM

Director of Education and Fellowship Training
Division of Rheumatology
Brigham and Women's Hospital
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts
*Rheumatoid manifestations of endocrine and lipid
disease*

Pauline Y.P. Ho, MBBCh (Hon), BSc, MSc, PhD, FRCP

Consultant Rheumatologist and Honorary Senior
Lecturer
The Kellgren Centre for Rheumatology
Manchester Royal Infirmary
The University of Manchester
Manchester, United Kingdom
Clinical features of psoriatic arthritis

Marc C. Hochberg, MD, MPH, MACP

Professor of Medicine and Epidemiology and Public
Health
Head, Division of Rheumatology and Clinical
Immunology
University of Maryland School of Medicine
Acting Director, Gerontology Research Education
and Clinical Center
Veterans Affairs Maryland Health Care System
Baltimore, Maryland
*Management of osteoarthritis
Pathophysiology of osteoporosis*

Jacqueline Hochman, MD, MSc, FRCPC

Assistant Professor
Rheumatology
University of Toronto
Toronto, Ontario, Canada
*Assessment of the patient with osteoarthritis and
measurement of outcomes*

Chelsea J. Hodgkiss-Harlow, MD

Physician
Family and Preventive Medicine
Integrative Medicine
University of California, San Diego
San Diego, California
*Principles of opioid treatment of chronic musculoskeletal
pain*

Robert W. Hoffman, DO, FACR

Senior Medical Fellow, Translational Medicine
Lilly Research Laboratories
Eli Lilly and Company
Indianapolis, Indiana
Overlap syndromes

Markus Hoffmann, PhD

Research Group Leader
University of Erlangen-Nuremberg
Department of Internal Medicine 3
Institute of Rheumatology and Immunology
Erlangen, Germany
Autoantibodies in rheumatoid arthritis

†Deceased

V. Michael Holers, MD

Professor of Medicine and Immunology
Medicine/Rheumatology
University of Colorado School of Medicine
Aurora, Colorado

Preclinical features of rheumatoid arthritis

Michael F. Holick, PhD, MD

Professor of Medicine, Physiology, and Biophysics
Section of Endocrinology, Nutrition, and Diabetes
Boston University School of Medicine
Boston, Massachusetts

Osteomalacia and rickets

Christopher Holroyd, BM, MRCP

Consultant Rheumatologist
MRC Lifecourse Epidemiology Unit
University of Southampton
Southampton, United Kingdom

Epidemiology and classification of osteoporosis

Oswaldo Hübscher, MD, MACR

Associate Professor of Medicine (Rheumatology)
Internal Medicine
Center for Medical Education and Clinical Research
Buenos Aires, Argentina

Pattern recognition in arthritis

David J. Hunter, MBBS, MSc, PhD, FRACP

Chair, Department of Rheumatology
Professor, Department of Medicine
Kolling Institute
University of Sydney
Staff Specialist
Rheumatology
Royal North Shore Hospital
St. Leonards, New South Wales, Australia

Assessment of imaging outcomes in osteoarthritis

M. Elaine Husni, MD, MPH

Vice Chair, Arthritis and Musculoskeletal Center
Department of Rheumatic and Immunologic
Diseases
Orthopedic and Rheumatologic Institute
Cleveland Clinic
Cleveland, Ohio

Classification and epidemiology of psoriatic arthritis

Robert D. Inman, MD

Professor
Medicine and Immunology
University of Toronto
Deputy Physician in Chief
Research Medicine
University Health Network
Toronto, Ontario, Canada

Reactive arthritis

Zacharia Isaac, MD

Director, Interventional Physical Medicine and
Rehabilitation
Harvard Medical School
Medical Director, Comprehensive Spine Care
Center
Brigham and Women's Hospital
Assistant Professor, Physical Medicine and
Rehabilitation
Harvard Medical School
Boston, Massachusetts

Lumbar spine disorders

Maura D. Iversen, BSc, MPH, DPT, SD

Professor and Chair, Physical Therapy
Northeastern University
Senior Instructor, Medicine
Harvard Medical School
Behavioral Scientist
Section of Clinical Sciences
Division of Rheumatology, Immunology, and
Allergy

Brigham and Women's Hospital
Boston, Massachusetts

*Arthritis patient education, health promotion, and team
approaches to management*

Autoantibodies in systemic lupus erythematosus

In this new edition of *Rheumatology*, the editors have again attempted to bring together a large group of world-renowned authors to provide essential information on the scientific basis of rheumatology and the definition, epidemiology, pathophysiology, clinical features, and management of all arthritic, musculoskeletal, and rheumatic disorders.

Rheumatology, Sixth Edition, builds on the success of the previous editions. As stated by Professor Jan Dequeker in his review of the fourth edition, “*Rheumatology* is the most comprehensive, authoritative rheumatology text designed to meet the complete needs of all practicing and academic rheumatologists as well as arthritis-related health care professionals and scientists interested in disorders of the musculoskeletal system. The edition is firmly grounded on modern medical science, integrating the relevant basic biology with current clinical practice, easily accessible, user-friendly, and a beautifully illustrated color publication.”

For this edition, every chapter has either been substantially revised or, in many cases, entirely rewritten, following a rigorous editorial policy to ensure that the content and format of the book remain consistent and meet the highest possible standards. Each chapter has been updated to incorporate a broad range of new information. Fourteen completely new chapters cover biomedical and translational science, disease and outcome

assessment, including new imaging modalities and early emerging disease, clinical therapeutics, and patient management and rehabilitation. The text has been streamlined, ensuring that each chapter contains the most critical and current information in the field, while supplemental materials (including extra tables, figures, and bonus text) are conveniently located online. The index has also been improved, making it easier for the reader to find topics of interest.

The production of this edition of *Rheumatology* has been a greatly enjoyable team effort. We would like to thank the authors who have contributed to this and previous editions of the book, as well as the excellent team at Elsevier, including Michael Houston, Kelly McGowan, and Louise King, among others. We look forward to bringing you a seventh edition in another 4 years.

Marc C. Hochberg
Alan J. Silman
Josef S. Smolen
Michael E. Weinblatt
Michael H. Weisman

ACKNOWLEDGMENTS

We would like to acknowledge the tremendous work of the contributors to this edition of *Rheumatology*, without whom this book would not have been possible. In addition, we would like to recognize our mentors: Drs. Eva Alberman, Alfred D. Steinberg, Georg Geyer, Ronald J. Anderson, Nathan J. Zvaifler, the late Harry Currey, Lawrence E. Shulman, Carl Steffen, Georg Geyer, and Mary Betty Stevens.

We would also like to thank the excellent team at Elsevier, including Kelly McGowan, Michael Houston, Louise King, Lou Forgione, and Brett MacNaughton, as well as our in-office editorial support (Jacqui Oliver, Aida Medina, Johanna Leibl, and Emily Moore) for all of their hard work and

diligence. Last, but certainly not least, we want to acknowledge our patients, who continue to provide stimulating challenges to us in our clinical practices.

Marc C. Hochberg
Alan J. Silman
Josef S. Smolen
Michael E. Weinblatt

THE SCIENTIFIC BASIS OF RHEUMATIC DISEASE

1

Epidemiologic concepts and classification of rheumatic and musculoskeletal conditions

■ DEBORAH P.M. SYMMONS

- Musculoskeletal epidemiology is concerned with the determinants and distribution of rheumatic and musculoskeletal conditions in different populations.
- The frequency of disease in a population can be expressed in terms of incidence (the number of new cases) and prevalence (the proportion of the population with the disease).
- Most rheumatic and musculoskeletal diseases are defined by using sets of classification criteria.
- Classification criteria are powerful tools for identifying and distinguishing patients with a target disease from those without the condition.
- The frequency and severity of rheumatic and musculoskeletal diseases vary with age, gender, ethnic origin, and country.
- Differences in disease or outcome frequency can be explored to yield hypotheses about demographic, genetic, hormonal, environmental, and psychosocial risk factors for the development or severity of disease.
- Such hypotheses are best tested in case-control or cohort studies that involve the use of a comparison group.

INTRODUCTION

Epidemiology is the clinical science that studies the distribution and determinants of disease in populations. It involves describing the frequency of diseases and their consequences (including morbidity and mortality) and understanding the risk factors for development of a disease or its complications. Two basic types of epidemiologic study can be performed:

- *Descriptive* epidemiology describes the number of people in whom the disease develops in a particular period or who currently have the disease, what type of people are susceptible (in terms of, e.g., age, gender, or ethnic background), and where and when the disease occurs (geographic variations on a large or small scale, secular trends).¹
- *Analytic* epidemiology tests hypotheses of causation and involves using a comparison group (Fig. 1.1). By comparing the frequency of a disease in people who have particular characteristics (e.g., exposure to certain drugs, pregnancy, or certain genotypes) or by comparing exposure characteristics in people with and without a particular disease or outcome, it is possible to identify risk factors for development of the disease or attributes that affect outcome or disease severity. In cohort studies, subjects are selected on the basis of their exposure status or being disease free and are observed to see in how many the disease develops. Cohort studies may be prospective, if the outcome

has not occurred when the study begins, or retrospective, if the outcome has already happened. In case-control studies, groups are selected on the basis of their disease status, those with the disease being the *cases* and those without being the *controls*. All the subjects are then studied to see how many in each group have been exposed to the risk factor or factors of interest. Each design has advantages and disadvantages, and the choice is often dictated by the relative prevalence of the disease and the exposure.²

This chapter introduces the fundamental concepts of epidemiology and describes how these concepts have been used to study the frequency of rheumatic and musculoskeletal disorders (RMDs) and their burden worldwide. It also discusses how hypotheses concerning risk factors for the development of RMDs or particular outcomes can be generated and tested.

DESCRIPTIVE EPIDEMIOLOGY—HOW MANY PEOPLE HAVE THE DISEASE?

The two most common measures of disease frequency are prevalence and incidence (Table 1.1).¹

Prevalence

Prevalence relates to existing cases of disease. *Point* prevalence is the proportion of the population who have the disorder at a particular point in time. This measure is useful for chronic persistent disorders such as rheumatoid arthritis (RA) and osteoarthritis (OA). For intermittent conditions such as back pain and gout, it is more appropriate to measure *period* prevalence—the proportion of the population who have the disorder at any time during a given period (usually 1 year). Finally, *cumulative* prevalence is the proportion of the population who have had or now have the disorder up to a specified time point (e.g., by 60 years of age) or up to the time of the study.

Prevalence in the population setting is commonly determined by conducting a survey via questionnaires, clinical evaluation, or a combination of both. Such questionnaires may be self-completed or administered by an interviewer. In the hospital or primary care setting, prevalence is often assessed by identifying diagnosed cases and relating them to the appropriate population base. Though practical for uncommon conditions,³ cases identified in this way are often skewed toward the more severe end of the spectrum. Increasingly, information on disease prevalence is derived from electronic health care record databases, with the denominator being the relevant proportion of the population covered by the database.

Incidence

The term *incidence* relates to the number of individuals in a defined population in whom the disorder first develops in a given period, typically 1 year.

Fig. 1.1 Comparison of case-control and cohort study designs.

TABLE 1.1
Measures of disease frequency

Term	Denominator	Numerator
Prevalence (relates to existing disease)	Number of people in the population	Point prevalence (number who have the disorder at a given time point) Period prevalence (number who have the disorder at some time during a given period) Cumulative prevalence (number who have the disorder at some time up to a given time point)
Incidence (relates to disease onset)	Total person-time of observation	First incidence (number who have their first onset of the disorder in a given period) Episode incidence (number of episodes of the disorder in a given period) Cumulative incidence (number who have their first onset up to a given time point)

This is known as the incidence rate or the *first incidence rate*. *Episode incidence* is the total number of episodes of a disorder in the defined population in a given period. The episode incidence of back pain is higher than the first incidence rate because it counts those who have repeated episodes during the time frame of interest. *Cumulative incidence* is the number of individuals who have ever had an episode up to a particular time.

Incidence is measured either by monitoring for new cases as they are diagnosed or by conducting two cross-sectional surveys some time apart and identifying new cases that have developed between the two surveys. Disease incidence and prevalence are related by the following formula:

$$\text{Incidence} \times \text{Duration} = \text{Prevalence}$$

Individuals may leave the prevalent pool of cases through either recovery or death. RA has a relatively low incidence but a long duration, so its prevalence is relatively high. The rate of death may be expressed as the *mortality rate* (the number of deaths from a disease in a given period divided by the total population) or the *case fatality rate* (the number of deaths from a disease in a given period divided by the number of cases of the disease).

Fig. 1.2 Problems in measuring disease frequency in patients with rheumatic and musculoskeletal conditions.

Practical issues in measuring disease frequency

Issues related to measuring disease frequency can be divided into those related to the numerator and those related to the denominator (Fig. 1.2).

Numerator

Case definition

Accurate estimation of incidence and prevalence depends on using standard nomenclature, a reliable case definition, and complete case ascertainment. The nomenclature in most widespread use is that adopted by the International Classification of Diseases (ICD).⁴ The ICD names diseases and groups them in a hierarchy on the basis of the body system. ICD10 is the version in current use.

Most RMDs do not have a specific diagnostic test, so sets of classification criteria (Table 1.2) have been developed to identify homogeneous patient populations for epidemiologic studies and clinical trials. These sets of classification criteria combine different types of information, including symptoms, signs, laboratory findings, imaging, genetic factors, and etiologic agents. Classification criteria have two purposes: first, to separate patients with the target disorder from normal subjects, and second, to distinguish patients with the target disorder from those with other similar disorders. In the majority of conditions, classification criteria should not be used for the diagnosis of individual patients.

Historically, most sets of classification criteria in rheumatology were developed by consensus and use of the physician's opinion as the "gold standard." A panel of experts compiled a list of candidate variables and then assessed their ability, either alone or in combination, to distinguish subjects who were judged by their physician to be cases from those judged not to be cases (either normal subjects or subjects with similar conditions). The assessment was done by determining the sensitivity and specificity of the criteria (Table 1.3). In more recent times, statistical techniques such as receiver operating characteristic curves, discriminant analysis, and logistic regression have been used to eliminate redundant variables and weight the individual characteristics to give maximum sensitivity and specificity. Classification and regression tree methodology enables the substitution of one variable for another (which helps when some data are missing) and enables attributes to be used more than once in different parts of the tree. In the recent development of new classification criteria for RA,⁴³ the decision to prescribe methotrexate to a patient with recent-onset synovitis was used as the gold standard, and a decision analysis software program⁴⁴ using discrete pairwise choices was used to assign weights to the categories within the selected criteria.

Many problems are encountered when interpreting and applying classification criteria. For example, early or mild cases may not meet the criteria. Furthermore, some criteria require expensive, invasive, or nonroutine investigations such as radiography or immunochemical tests. This makes it difficult to apply the criteria retrospectively using patients' medical records or to use them unaltered in population surveys.

For inflammatory conditions such as RA or systemic lupus erythematosus (SLE), the criteria were developed by studying patients with active disease. A population survey of the prevalence of RA will therefore identify individuals who currently have active disease plus those who in the past have had disease that was sufficiently severe to leave stigmata such as joint

TABLE 1.2

Classification criteria for rheumatic diseases

Name of disease	Name of classification criteria
Ankylosing spondylitis	New York criteria ⁵ Modified New York Criteria ⁶ ASAS criteria for axial spondyloarthritis ⁷

deformities. People who had mild disease that is now in natural or drug-induced remission will not be detected. Thus, the resultant estimate is a cross between point prevalence and cumulative prevalence.

Finally, although prevalence does not affect the sensitivity and specificity of the classification criteria, it does affect their positive predictive value (see Table 1.3). In the example given in Table 1.4, the proportion of positives that are falsely positive is 2% in the clinic setting and 66% in the population setting.

Determining the date of onset

Determining the time of disease onset is problematic for some RMDs. If OA is defined in terms of radiologic change, it is usually impossible to say when it first appeared. For conditions such as SLE the onset date is often defined as the (arbitrary) date on which the classification criteria were first met. In RA the onset date may be defined as the date of first symptoms, but this may be difficult for patients to recall. When comparing studies it is important to take note of any different definitions of onset date.

Completeness of ascertainment

Finally, all cases of the disease within the population should be identified. Disease in the population has a continuum of severity (Fig. 1.3) and ascertainment may not be complete, depending on where it is carried out. Clinic-based studies rely on the patient having sought medical care, the condition being diagnosed (more or less) correctly, and the patient being referred to the appropriate specialist. To maximize ascertainment, several approaches may be used simultaneously (e.g., ascertaining SLE cases from hospital clinics, self-help groups, and laboratory records of antinuclear antibody screening) in an attempt to capture all cases.

Denominator

The size of the population from which the cases have been identified is difficult to determine when cases are identified only from the hospital or from clinic attenders and there is no defined catchment population. Many factors determine whether an individual case is referred to a particular center (referral bias).

The denominator population should consist of only individuals at risk for development of the disease. Thus, the incidence of juvenile idiopathic arthritis should be expressed per 100,000 children 16 years and younger. A frequently encountered error is to apply the prevalence rate (e.g., for RA) measured in the adult population to the total population for estimating the total number of cases in the population. This assumes that the prevalence of RA is the same in children as in adults (which is not the case).

Sources of data for estimating disease occurrence

Routinely collected data may prove useful in building a picture of the epidemiology of RMDs, although assessment of the diagnostic accuracy and level of completeness of these data is essential. Examples are included in the following sections.

Death certificates

Mortality records have, with few exceptions, been of little use in RMD epidemiology because RMDs are an infrequent cause of death. RMDs are often

not recorded on the death certificate, and thus estimating, for example, how many people with RA die each year is impossible. However, death certificates will provide valuable information on the number and causes of death in an identified RA cohort. Using the ICD, comparisons of the attributed causes of death among RA cohorts in different locations and between RA cohorts and the general population are possible.

Morbidity registers

Even though many countries have cancer registers, the same is not generally true for RMDs. Some Scandinavian countries have registers of people who are admitted to hospital or seen in a clinic with a particular diagnosis or who can claim reimbursable medication, and by using a unique personal identity number, investigators are able to link information on these registers with, for example, mortality data. The Mayo Clinic in Rochester, Minnesota, has developed a record linkage system whereby the health care records of all residents in Olmsted County are maintained in a central database.⁴⁵ Information from this database, which dates back to 1910, has been used to generate incidence estimates for a number of RMDs. However, the population of Olmsted County is only about 100,000 and the majority of the population is of Scandinavian descent. The former limits the reliability of estimates for rare diseases and the latter, the generalizability of all estimates because the residents of Olmsted County are not representative of the general U.S. population.

Health care provider databases

In some countries, health care that is reimbursed by the government or insurance companies is linked to diagnostic codes on large computerized e-health databases. Such databases have provided a rich source of data on the frequency of rare events (e.g., drug toxicity or major complications of orthopedic surgery). Examples from the United States include Medicare and data from health maintenance organizations such as Kaiser Permanente. In the United Kingdom, the General Practice Research Database (now part of the Clinical Practice Research Database, www.cprd.com) and The Health

TABLE 1.3

Sensitivity, specificity, and positive and negative predictive values of criteria sets

		Disease—by “gold standard”	
		Yes	No
Criterion or criteria set	Positive	a (true positive)	b (false positive)
	Negative	c (false negative)	d (true negative)
Sensitivity: proportion of cases identified correctly		$\frac{a}{a+c}$	
Specificity: proportion of noncases identified correctly		$\frac{d}{b+d}$	
Positive predictive value: proportion with a positive test who have the disease		$\frac{a}{a+b}$	
Negative predictive value: proportion with a negative test who do not have the disease		$\frac{d}{c+d}$	

Fig. 1.3 Sources of cases from a community.

TABLE 1.4

Influence of prevalence on positive predictive value

		Clinic setting			Population setting		
		Prevalence of target disease—50%			Prevalence of target disease—1%		
		Gold standard			Gold standard		
Criteria		Yes	No		Yes	No	
	Positive	490	10	500	98	188	286
	Negative	10	490	500	2	9702	9704
		500	500		100	9900	
		Positive predictive value—98%			Positive predictive value—34%		
		% False positives—2%			% False positives—66%		

Improvement Network (www.thin-uk.com) provide pooled anonymous patient data from a large number of practices of general practitioners. In all these situations, information about the denominator—the number of people covered by the registers—is known, but standard disease definitions are not generally used.

Work absenteeism records

In some countries, information on the reason for and duration of absence from work for sickness is recorded and can be used to examine the profile of musculoskeletal complaints in the workforce.

Population health surveys

Many countries have regular population surveys (called *health interview surveys*) that examine social and demographic trends. These surveys may include health-related information such as the number of visits to a physician, self-reported illness, and disability. Examples include the General Lifestyle Survey (formerly the General Household Survey) in the United Kingdom. Sometimes an examination phase is included (a *health examination survey*). Examples include the National Health and Nutrition Examination Surveys in the United States (www.cdc.gov/nchs/nhanes.htm). There is a move to try to standardize the questions used in health interview surveys across countries to facilitate comparisons.

ANALYTIC EPIDEMIOLOGY—WHO IS SUSCEPTIBLE TO THE DISEASE?

Differences in disease occurrence arising from descriptive epidemiology (e.g., the twofold greater incidence of RA in females⁴⁶ and the rare onset of ankylosing spondylitis after the age of 55⁴⁷) may hint at causes. It is important to account for population differences in age (e.g., 10-year age bands) and gender before making inferences. This can be done by applying the age- and sex-specific incidence rates from one population (the *standard*, often the national population) to the age and sex distribution of another population (the *index*) to calculate an overall rate in the latter, assuming that the age and gender distributions are identical.

Increased frequency or adverse outcomes may also be found in specific ethnic groups (e.g., SLE in people of African ancestry),⁴⁸ occupations (e.g., hip OA in farmers),⁴⁹ and socioeconomic groups (e.g., back pain in lower socioeconomic groups).⁵⁰ It can be difficult, however, to determine the relative contributions of these factors because they are often interrelated.

WHERE DOES THE DISEASE OCCUR?

Differences in disease rates between countries or regions may be due to genetic, other host-related, or environmental factors (or any combination of such factors). Possible environmental factors include macroenvironmental variables such as air and water pollution, microenvironmental factors such as diet and smoking, and socioeconomic factors. Migration studies may suggest whether geographic differences in disease frequency are predominantly due to genetic or environmental factors. If a migrating population has the same frequency of disease in its native and newly adopted countries, this suggests that genetic factors are more important. If the disease frequency changes, especially if it changes within one or two generations, this suggests a change in environment or lifestyle as being important.

There are hints of geographic patterns for a number of RMDs, which are still being unraveled (Table 1.5). First, RA occurs with similar frequency in most white populations. However, it has a higher prevalence in some Native Americans such as the Pima and a lower prevalence in West Africa, China, and Indonesia.⁵¹ Second, most of the geographic variation in the frequency of ankylosing spondylitis can be explained by the varying prevalence of HLA-B27 in different racial groups. By contrast, it is more difficult to explain the ethnic variation in SLE, although investigation of the frequency and clinical characteristics of SLE in people of African origin can yield important etiologic clues. The frequency of SLE is high in African American and African Caribbean populations but lower in West Africans.⁴⁸ Although this suggests an environmental cause of SLE, it is possible that genetic admixture⁵² may play a part in the changing incidence of SLE in this group of people.

WHEN DOES THE DISEASE OCCUR?

Time trends in disease occurrence may also provide important etiologic clues. Clusters of incident cases in a particular season of the year or sporadic time-space clusters suggest that all or most of the cases in the cluster may

TABLE 1.5
Variations in rheumatic and musculoskeletal disease frequency versus European whites

	Increased frequency	Decreased frequency
Rheumatoid arthritis	Native American (Pima, Chippewa, Yakima)	Rural African Chinese Indonesian
Juvenile idiopathic arthritis	Canadian Inuit	African Americans
Ankylosing spondylitis	Haida people	Australian aboriginals African Americans
Gout	Polynesians Filipinos	Africans
Systemic lupus erythematosus	African Americans African Caribbeans Asian Indians Chinese	West Africans
Scleroderma	Southern United States	Australian aboriginals
Polymyalgia rheumatica	Northern European whites	African Americans
Osteoarthritis of the knee	African American women	
Osteoarthritis of the hip		Chinese Japanese Asian Indians Africans
Osteoporosis	Northern Europeans	Africans

have been exposed to an etiologic agent from a common source. Lyme disease provides a good example of a disease identified because of clustering of cases of juvenile and adult inflammatory arthritis in place and time.⁵³ A rise or fall in disease incidence annually may suggest a change in the level of exposure to risk factors. Between around 1970 and 1985 the incidence of RA in women fell in the United States and United Kingdom. This coincided with increasing use of oral contraceptive pills, and some evidence suggests that the two phenomena are linked.⁵⁴ Changes in disease prevalence with time are more difficult to interpret because they may be caused by alterations in disease incidence, recovery rates, survival, or a combination of all three. Health care planners must take into account trends in incidence and prevalence, both of which may be affected by increasing life expectancy. For instance, the number of new cases of hip and knee OA in most Western countries is rising steeply. This is due more to the aging population than to any change in age-specific incidence.

WHY DOES THE DISEASE OCCUR?

Descriptive epidemiologic studies can generate hypotheses about disease causation, but they cannot test these hypotheses. Analytic studies are required to investigate the relationship between exposure to a risk factor (environmental or genetic) and development of disease. As discussed earlier, such studies may be retrospective or prospective (see Fig. 1.1). In a prospective study, individuals are identified and classified according to their exposure status before development of the disease. However, it is sometimes possible to assemble such cohorts retrospectively after development of the disease, for example, by using records of occupational exposure (e.g., to vinyl chloride) or immunization (e.g., rubella vaccine).

A cohort study is more efficient when investigating a rare exposure, whereas a case-control design is more efficient when investigating a rare disease (Table 1.6). A case-control study is best for investigating multiple risk factors simultaneously. Incident cases are usually preferred over prevalent cases because any risk factors identified are markers for disease susceptibility rather than persistence. For example, clinic attenders with RA have a much higher frequency of the *shared epitope* than the general population does. Furthermore, combinations of shared epitope alleles (e.g., 0404 homozygosity) are associated with a particularly poor outcome of RA. However, in studies that are confined to incident cases of RA, the association with the shared epitope is only modest.

The most difficult aspect of a case-control study is selection of appropriate controls. Controls should be individuals who would have been included among the cases if the disease had developed and hence should be selected from the same catchment population.

TABLE 1.6
Advantages and disadvantages of various epidemiologic study designs

Study design	Advantages	Disadvantages
Prospective cohort	Good exposure data Accurate timing of exposure and disease onset Little recall bias	Expensive May be long delay before disease onset Large numbers needed Only suitable for frequent outcomes
Case-control	Relatively inexpensive Quick to perform Useful for rare diseases	Subject to recall bias Cases may not be representative Controls difficult to select and ascertain Exposure data may be unreliable Time of exposure and disease onset may be imprecise
Cross-sectional	Generalizable Quick to perform	Difficult to distinguish cause and effect Biased toward inclusion of chronic cases

The results from longitudinal studies are usually expressed as a relative risk or risk ratio (i.e., risk for [or incidence of] the disease in the exposed cohort $\frac{a}{a+b}$ divided by risk for disease in the unexposed cohort [$\frac{c}{c+d}$; see Table 1.3]). In a case-control study, however, the relative frequency of risk factors is compared between the cases and controls, and thus in this situation the odds ratio is calculated (i.e., the odds of exposure given disease $\frac{a}{c}$ divided by the odds of exposure given no disease $\frac{b}{d}$). The relative risk or odds ratio indicates the strength of the association between the risk factor and the disease. In a case-control study, causality cannot be assumed because information about disease state and exposure status is collected cross-sectionally or retrospectively. It is therefore impossible to be certain which came first. In a longitudinal study, the higher the relative risk, the more likely the exposure and the outcome to be linked in a causal chain. Box 1.1 shows the other factors that should be considered when examining causality.

CLINICAL EPIDEMIOLOGY—WHAT HAPPENS TO PEOPLE WITH THE DISEASE?

Investigation of prognosis is analogous to investigation of development of the disease and can be assessed with either cohort or case-control studies. In prognosis studies, all the individuals studied have the disease in question. In longitudinal studies, patients are selected on the basis of exposure to a predictor variable (e.g., anti-citrullinated peptide antibody positive in RA) and then monitored for the incidence, in those with and without the

TABLE 1.7
Some etiologic, protective, and prognostic environmental factors in rheumatic and musculoskeletal disease

Condition	Etiologic factors	Protective factors	Risk factors for a poor prognosis
Rheumatoid arthritis	Smoking Periodontitis Obesity Exposure to silica dust Breastfeeding Female gender	Oral contraceptive use Alcohol consumption High fruit intake	Rheumatoid factor Anti-citrullinated protein antibodies HLA-DR4
Ankylosing spondylitis	HLA-B27 Male gender		
Gout	Hyperuricemia Thiazide diuretics Fructose Lead exposure	Low-fat dairy products Regular heavy coffee consumption	
Systemic lupus erythematosus	Complement deficiency African origin Some drugs (e.g., hydralazine) Female gender Ultraviolet light		Lower socioeconomic status
Scleroderma	Silica exposure Organic solvents Some drugs (e.g., bleomycin) Female gender		
Osteoarthritis of the knee	Obesity Joint malalignment Trauma Certain occupations Female gender	Smoking	Obesity
Osteoarthritis of the hip	Childhood hip disease (e.g., Perthes) Trauma Certain occupations (e.g., farming) Hip dysplasia		
Back pain	Obesity Certain occupations Driving		Previous back pain Psychological factors
Osteoporosis	Early menopause Low body mass index Smoking Excessive alcohol intake Physical inactivity Corticosteroid use	Obesity African origin Exercise	Falls

BOX 1.1 ASSESSING CAUSALITY BETWEEN A RISK FACTOR AND A DISEASE OR OUTCOME

An association between an exposure and an outcome may be due to

- Direct causation
- Chance
- Bias
- Confounding

Causality is more likely if

- Exposure precedes the outcome of interest
- Association is biologically plausible
- Association is strong (high relative risk)
- Association is consistent between studies
- Association is supported by experimental evidence

predictor, of the outcome of interest (e.g., death). Longitudinal observational studies may be subject to left or right censorship.

- Left censorship, a bias in recruitment, occurs when, for example, subjects are recruited as consecutive prevalent cases from a hospital clinic. Patients with mild disease who have been discharged from follow-up and those who have severe disease and have died will be underrepresented in the cohort.
- Right censorship, a bias in follow-up, occurs, for example, in a follow-up study when subjects have been lost to follow-up.

In a case-control study of outcome, patients are selected on the basis of whether a particular complication of their disease has developed (e.g.,

lymphoma in RA or vertebral fracture in osteoporosis) and then compared with patients without this outcome for predictors such as corticosteroid use.

A summary of some of the etiologic, protective, and prognostic factors for selected rheumatic diseases is shown in Table 1.7. The evidence for some of these factors is more definitive than for others.

Determining absolute risk, attributable risk, and population attributable risk fraction

The size of the relative risk indicates the strength of association between an exposure and outcome but not the relative importance of the exposure to the overall prevalence. Patients with Sjögren syndrome have a relative risk of 44 for the development of non-Hodgkin lymphoma with respect to the general population.⁵⁵ However, non-Hodgkin lymphoma develops in few patients with Sjögren syndrome given the former's rarity in the general population.

From a patient's perspective, it is the absolute risk for development of a disease or outcome that is key. From a public health perspective, two other measures are more important: attributable risk and the population attributable risk fraction.

- Attributable risk is the difference between risk for the outcome in the exposed and in the unexposed. It gives an estimate of the number of cases in an exposed population that can be attributed to the exposure.
- The population attributable risk fraction is the proportion of cases of the disease in the population that can be attributed to the risk factor (and thus could be prevented if the risk factor were eliminated). For example, it has been estimated that 35% of cases of seropositive RA are attributable to smoking.⁵⁶

Principles of clinical outcome assessment

■ NICHOLAS BELLAMY

- Measurements of symptom severity, disease activity and consequence, and adverse effects of treatment as well as global assessments are all commonly used.
- Outcome measures must be valid, reliable, responsive, and feasible, and should be brief, simple, and easy to score, particularly for use in routine clinical care.
- The choice of outcome measures depends on disease state, the therapeutic repertoire of the intervention(s) exhibited, and whether they are to be used for research or routine practice.
- Core sets of outcome measures have been recommended for use in clinical trials for several rheumatic diseases.
- Clinical benchmarks are emerging against which the treatment response can be interpreted at the individual patient level.

INTRODUCTION

Measurement forms an essential component of health care at all levels, from the treatment of individual patients to policy development. The measurements may provide descriptive information or play a role in evaluation of response to treatment or in prognostication. The focus of this chapter is on evaluating clinical health status in individual patients and groups of patients; that is, aspects of the condition that can be appreciated through questioning and clinical examination. In addition to allowing evaluation of individuals and groups of patients, clinical outcome measures find important applications in making formal assessments of the impact of health care decisions on health care costs, quality of care, quality of life, and burden of disease, as measured by morbidity and mortality in the population. Such assessments are an integral part of health care delivery systems. A list of abbreviations related to clinical measurement that are used in this chapter can be found in [Box 2.1](#).

CLINICAL OUTCOME ASSESSMENT:
A CONCEPTUAL FRAMEWORK

Clinical outcome measures examine the clinical consequences of a disease or disorder in terms of mortality (survivorship) and morbidity (symptom severity, impact of the condition on various aspects of health-related quality of life, negative consequences of treatment). In painful musculoskeletal conditions the impact on function is particularly important, as is the bidirectional relationship between perceived pain and emotional well-being. The paradigm of the “5 Ds”—death, disability, discomfort, drug (or other iatrogenic) reactions, and dollar (or economic) costs—advanced by Fries encompasses outcomes that are relevant to all patients because they are discernible at the individual patient level, represent the key consequences of disease and its treatment, and are the ultimate outcomes of the disease process.¹ The components of health and the consequences of arthritis and musculoskeletal conditions are many and diverse. It is possible to measure multiple aspects of a patient's condition with evaluation procedures that are relevant to specific clinical conditions and assessment and measurement environments, and are aligned with assessment objectives.

It is important to appreciate that in the discipline of clinical measurement (synonym: clinical metrology) there is variable use of common terminology.

The terms *endpoint* and *outcome* are used interchangeably. However, the terms *instrument* and *tool* can refer not only to electromechanical devices but also to questionnaires and other assessment techniques. The questionnaires, in turn, are variably referred to as *health status questionnaires*, *health status measures*, or *health status instruments*. The terms *subjective* (soft) and *objective* (hard) are best avoided, and instead the measurement technique should be referred to according to its qualitative (e.g., type of measure, purpose of measurement) and quantitative (e.g., reliability, validity, responsiveness) measurement characteristics.

Outcome measures may be divided into two broad categories: observer dependent (or assessor rated) and observer independent (or self-rated). In general, observer-independent clinical measures are based on self-administered questionnaires, usually referred to as *patient-reported outcome measures* (PROMs). In contrast, observer-dependent clinical measures include interviewer-scored questionnaires, physical examination findings, and tests of performance rated using technical instruments (e.g., grip strength, walk time). Certain techniques, such as face-to-face interview, walk time, grip strength, and articular index, involve an interaction between the assessor and the patient, which on occasion may bias the result obtained.

A fundamental aspect of measurement is whether all patients will be asked the same questions on every occasion, or whether the questions asked should be adapted to individual patients or the response patients give to initial questions should determine the nature of subsequent questions, using computer adaptive testing. The National Institutes of Health are currently exploring aspects of this issue in the Patient-Reported Outcomes Measurement Information Systems (PROMIS) initiative.²⁻⁴ This initiative has resulted in the development of item banks that form the basis of an alternative approach to index construction and presentation.

FUNDAMENTAL PRINCIPLES OF CLINICAL
OUTCOME ASSESSMENT

Outcome measurement procedures should fulfill three major criteria that are encompassed by those proposed by the Outcome Measures in Rheumatology Clinical Trials (OMERACT) group, as the OMERACT filter.¹ The three components of the filter are “truth,” “discrimination,” and “feasibility.” Truth concerns issues of validity, discrimination addresses issues of both reliability and responsiveness, and feasibility encompasses ease, time, cost, interpretability and arguably ethics. Measurement processes that are potentially hazardous to patients raise ethical issues that must be explained to and understood and accepted by patients and study participants. The importance and necessity of acquiring new information should be weighed against any attendant risks.

Validity

Validity is a measure of the extent to which an instrument specifically measures the phenomenon of interest. In contrast, reliability defines the extent to which the measurement procedure yields the same result on repeated determinations. Validity and reliability are separate clinimetric issues, and it does not follow that because a measure is reliable it is also valid or vice versa ([Fig. 2.1](#)). More specifically, validity is concerned with sources of nonrandom error (i.e., systemic error or bias), whereas reliability is concerned with sources of random error, also known as *noise*. Systemic error or bias may prevent an instrument from truly measuring what is intended, which results in inaccuracy. A number of different strategies may be employed to determine validity, each conceptually different and relying on different methods of assessment. There are four types of validity: face, content, construct, and criterion.

SCHEMATIC REPRESENTATION OF SYSTEMIC ERROR (BIAS) AND RANDOM ERROR (NOISE)**Fig. 2.1** Differentiation of systemic error (bias) and random error (noise).**Face validity**

A measure has face validity if experts judge that it measures at least part of the defined phenomenon. In many instances this is self-evident, whereas in others, particularly in questionnaire-based measures of functional status, it may not be entirely obvious whether the measurement reflects physical, social, or emotional function.

Content validity

An instrument can have face validity but fail to capture in its entirety the dimension of interest. Content validity, therefore, is a measure of comprehensiveness—the extent to which the measure encompasses all relevant aspects of the defined attribute. Content validity is generally determined by group consensus (e.g., nominal or Delphi techniques). The decision regarding which items should be included in a questionnaire-based instrument and which should be excluded is critical, because it defines the nature of the instrument and its future applicability. Any subsequent addition or deletion results in an instrument that requires further validation.

Given the variability in symptom expression by patients, one of two approaches can be employed to achieve comprehensiveness in questionnaire-based measures. The first is to include a standard battery of measures that probes frequently occurring symptoms that are clinically important to the majority of patients. In the second approach, the measurement process is tailored to the individual by measuring only those items that are important to that particular person. The issue of importance can be decided by patients, who rate the importance of their symptoms, or by clinical assessors, whose decision is based on their perception of the patient's symptoms.

Construct validity

Construct validity is of two types: convergent and discriminant. Both are tested by demonstrating relationships between measurement scores and a theoretical manifestation (i.e., construct or consequences of an attribute) of the disease. Convergent construct validity is assessed by the statistical

correlation between scores on a single health component, as measured by two different instruments. If the correlation coefficient is positive and appreciably above zero, the new measure is said to have convergent construct validity. In contrast, discriminant construct validity testing compares correlation coefficients between scores on the same health component, as measured by two different instruments (e.g., separate measures of physical function) and between scores on that health component and each of several other health components (e.g., measures of social and emotional function). A measure has discriminant construct validity if the proposed measure correlates better with a second measure, accepted as more closely related to the construct, than it does with a third, more distantly related measure.

Criterion validity

Criterion validity is assessed by statistically testing a new measurement technique against an independent criterion or standard (concurrent validity) or against a future standard (predictive validity). Criterion validity is an estimate of the extent to which a measure agrees with a gold standard (i.e., an external criterion of the phenomenon being measured). The major problem in criterion validity testing, for questionnaire-based measures, is the general lack of gold standards. Indeed, some purported gold standards may not themselves provide completely accurate estimates of the true value of a phenomenon. In contrast, electromechanical devices such as those evaluating strength, resistance, and range of movement can more often be validated using standard calibration techniques found in the engineering literature.

Reliability

Consistency, reproducibility, repeatability, and agreement are synonyms for *reliability*. Reliability is the extent to which a measurement procedure yields the same result on repeated determinations (see Fig. 2.1). These determinations may be either different measurements performed at the same time (internal consistency) or the same measurements performed at different times (stability). Repeated measurements are rarely exactly the same, because there is usually some random error, noise, or degree of inconsistency. There are various methods of calculating reliability, each method reflecting a different aspect of instrument performance, so that different coefficients are derived using different methods. Defined sources of measurement error include the subject, the assessor, and the measuring instrument. Patient variability often arises from normal variation in symptoms or from fatigue or inattention. When observers are involved in capturing information, both interobserver and intraobserver reliability are important. Observer variability may be the result of inadequate standardization, the necessity for complex judgments, perceptual elements, or fatigue. When technical instruments are involved in the measurement process, variation in, for example, the cuff configuration of a modified sphygmomanometer or in the mechanical resistance of a dynamometer or dolorimeter may be important sources of error.

Responsiveness (sensitivity to change)

The primary goal of outcome assessment in evaluative research is to detect clinically important changes in some aspect of a condition. To detect change, a measurement technique needs to be targeted to aspects of the disease amenable to change, using content and scaling methods that allow detection of change, and be applied at a point in time when change might have occurred. Validity and reliability are important aspects of all measurement techniques, but the capacity to detect change is the quintessential requirement of a successful outcome measure for evaluating change over time and the patient's response to treatment. An assessment technique may fail to record any clinical improvement for a number of reasons (e.g., patient lacks response potential, lacks compliance with the treatment program, or has received inefficacious treatment; the outcome measure is insensitive; or a type II error occurs due to inadequate sample size).

STATISTICAL ISSUES

It is necessary to have a basic understanding of the statistics used in the development and validation of health status measures. Although correlation coefficients are frequently used, they are a measure of the strength of association, not a measure of agreement, so that it is possible to have perfect correlation but zero agreement between two measurements. In evaluating construct validity using correlation coefficients, both strength and direction should be considered *a priori*; otherwise, data interpretation can become complex and biased.

The following are commonly used statistical tests for evaluating reliability, validity, and responsiveness:

- Bland and Altman scatter plots permit the distribution of pairwise data to be appreciated.
- The Cohen κ statistic, a metric reflecting agreement beyond chance, can be weighted or unweighted and adjustments made for bias and prevalence.
- Intraclass correlation coefficients are often used in intrarater and interrater agreement analyses, based on continuous data.
- The Cronbach α statistic, a measure of average interitem correlation, is used to evaluate internal consistency.
- Factor analysis is a useful procedure for evaluating structure provided the sample is sufficiently large and is also representative. Repeated factor analyses on the same instrument using different data sets may yield conflicting results.
- Rasch analysis is increasingly being employed to test outcome scales against mathematical models using a probabilistic form of hierarchical or Guttman scaling. The Rasch model attempts to scale variables along a continuum, but not all Rasch analyses of the same instrument necessarily agree with one another. Although, in general, individuals who can perform tasks of a particular degree of difficulty should be able to perform all tasks of lesser difficulty, this is not always the case.
- A number of techniques, including interperiod correlation matrix analysis, may be used to estimate measurement error, which can in turn be used to evaluate change beyond measurement error.
- ANOVA (analysis of variance) and Student's *t*-test are commonly used to evaluate responsiveness.
- Effect size (change score/baseline standard deviation) is used to evaluate responsiveness.
- Standardized response mean (change score/change score standard deviation) is used to evaluate responsiveness. Responsiveness, whether evaluated by ANOVA, Student's *t*-test, effect size or standardized response mean may differ between outcome measures used to evaluate different variables or even the same variable and may differ even within an outcome measure when it is presented in different scaling formats.
- Relative efficiency (square of the ratio of two *t* or *z* statistics) is used to evaluate relative responsiveness.

OUTCOME ASSESSMENT MEASURES FOR MUSCULOSKELETAL DISORDERS

There are numerous techniques for assessing the beneficial and adverse outcomes of treatment. Some health status instruments have been developed specifically to assess certain conditions (condition-specific measures), whereas others have been developed to permit measurement across several or many diseases (generic measures). Readers interested in specific measurement issues should consult standard measurement texts. In this section a review is presented of the measurement of pain, impairment, ability/disability, and participation/handicap; patient and physician global assessments; multidimensional health status instruments (quality of life, utility); and measures of adverse drug reactions. Readers should refer to other sections of this textbook for information on laboratory-based and imaging-based measurement procedures.

Pain

Pain is an entirely subjective phenomenon, the perception of which is modulated by a variety of influences, and results in pain behaviors that may be observed. The severity of perceived pain can be rated only by the sufferer. In contrast, pain behavior can be rated by a trained assessor. Complex bidirectional interactions occur between pain and other factors, including personal factors unique to the individual. Pain can be assessed using a variety of techniques (Fig. 2.2), including the following:

- Likert or adjectival scales
- Visual analogue scales
- Ladder scales, numerical rating scales
- Chromatic continuous analogue scales
- Pain faces scales
- McGill Pain Questionnaire
- Behavioral observation techniques

Comparative studies of pain rating scales in rheumatoid arthritis (RA) and osteoarthritis (OA) suggest that there is a positive relationship between

Fig. 2.2 Adjectival, numerical, and visual scales for rating pain.

initial pain rating and subsequent pain relief scores and that all the aforementioned types of scales are responsive. Likert and visual analogue scales are the most frequently applied types of scales. Likert scales usually employ an odd number of descriptors (3, 5, 7, or 9), whereas visual analogue scales are most often 100 mm long and horizontal in orientation, with terminal descriptors. The numerical rating scale is often scaled from 0 to 10, displayed in linked boxes, and has terminal descriptors. The focus, phraseology, descriptors, and time frames for recall used in such scales often vary among different questionnaires. In comparative studies in RA and OA, the single-item global numerical rating pain scale appears comparable in responsiveness to the same question presented on a visual analogue scale and is slightly more responsive than the corresponding five-point Likert scale.

When pain scales are applied, it is important to specify either the global nature of the question or the specific aspect of pain that is being assessed (e.g., while stair climbing, while walking, at rest, during the night, overall) and clearly indicate the time interval over which pain is being evaluated (e.g., previous 48 hours, 1 week). Several of the standard established segregated multidimensional health status instruments, including the Health Assessment Questionnaire (HAQ),⁵ Arthritis Impact Measurement Scales (AIMS) and AIMS2,^{6,7} Western Ontario and McMaster (WOMAC) Osteoarthritis Index,⁸ and Australian-Canadian (AUSCAN) Hand Osteoarthritis Index,⁹ contain distinct pain subscales. These contrast with other instruments that either contain no pain subscale (e.g., Functional Index for Hand Osteoarthritis [FIHOA],¹⁰ Cochin index¹¹) or in which pain is an integral part of an aggregated scoring system combining scores on several different dimensions (e.g., Indices of Clinical Severity [ICS]).¹² It should be noted that the recall period differs among measures. A short recall period may offer advantage when the intervals between repeat assessments are short.

Impairment, ability/disability, and participation/handicap

The terms *impairment*, *disability*, and *handicap* may be confused in everyday usage, even though the World Health Organization (WHO) has previously characterized these three different entities.¹³ *Impairment* is defined as any loss or abnormality of psychological, physiologic, or anatomic structure or function. It signifies that a pathologic state has reached a stage of detectability. In contrast, *disability* includes any restriction or lack of ability to perform an activity in the manner considered normal. Such disabilities include alteration in behavior and interactive processes such as communication, as well as strictly physical function. A *handicap* is manifest as a disadvantage experienced by an individual as a result of an impairment or

disability, such that it limits or prevents the fulfillment of a role considered normal for that individual. In essence, therefore, impairment occurs at an organ level (intellectual, sensory, visceral, musculoskeletal), disability occurs at a personal level (behavior, self-care, locomotion, dexterity), and handicap occurs at a social level (independence, geographic mobility, employability, social integration).¹³ The concepts of disability and handicap, in particular, are considered unipolar; and partly for this reason the newer WHO International Classification of Functioning, Disability, and Health (ICF) is to be preferred, because it considers these same concepts in a bipolar framework of ability and participation.¹⁴ The ICF framework proposed by the WHO is particularly useful in conceptualizing the functional impact of many of the conditions described in other chapters of this text. The ICF framework considers a hierarchy of impairments, activities, and participation, modulated by contextual factors (environmental and personal), and extends the original WHO classification of impairment, disability, and handicap to incorporate positive aspects of health, including physical activity and participation in society.¹⁴ Several more modern outcome measures have been mapped to the ICF framework.¹ The ICF framework may also provide a construct on which to base instrument development.

Impairment

In clinically based musculoskeletal applications in research and practice, measurement is often directed at the assessment of abnormalities in structure (e.g., swelling, tenderness). The most important examination-based measurement procedure is the separate enumeration of swollen and tender joints in patients with inflammatory polyarthritis.¹ The usual method employs separate counts of the number of swollen and tender joints using either the American College of Rheumatology (ACR) 68-joint count or the European League Against Rheumatism (EULAR) 28-joint count. The 28-joint count is often conducted as part of determining the 28-joint Disease Activity Score (DAS28).

It is convenient to chart individual joint involvement on a homunculus or mannequin (Fig. 2.3), as is the practice with the DAS28. Other methods have been developed for scoring joint involvement in OA, enthesopathy in ankylosing spondylitis (AS), and tender points in fibromyalgia.¹ Methods for assessing other clinical signs, such as heat, erythema, and crepitus, have been less rigorously studied. All such procedures are liable to interrater and intrarater error and are best performed by skilled standardized assessors. Nevertheless, various impairment assessments can be conducted at acceptable levels of reliability by trained assessors.

The American Medical Association *Guides to the Evaluation of Permanent Impairment*^{14a} provides a standardized method to rate impairment at maximum medical improvement. However, the guides are primarily employed in compensation/litigation applications, and different jurisdictions may use different versions of the guides.¹⁵

Ability/Disability

Functional measures can be subdivided into those based on observed tests of performance and questionnaires that assess functional capacity.

Performance-based measures

Performance-based measures might at first seem the most direct way to assess the patient's function. However, such measures often involve an interaction between the assessor and subject that may augment or diminish the true performance and raise concern regarding intra-assessor and inter-assessor consistency and the need for assessor standardization. Furthermore, change in performance on the performance test may not correspond to a comparable change in the performance of relevant activities of daily living. The relevance of the change to the patient may therefore require interpretation. Nevertheless, some measures, such as the modified Schober test in AS, grip strength in RA, and range of movement in knee OA, remain in common usage in clinical rheumatology. In health disciplines such as orthopedic surgery and physiotherapy extensive use is made of performance-based measures in the routine management of patients with bone and joint diseases.¹ Interrater and intrarater reliability have been quantified and standard procedures developed to train assessors and perform the evaluations.

Capacity-based measurement

Patients with musculoskeletal disorders may experience three types of functional disability: physical, emotional, and social. All three forms are amenable to outcome assessment using valid, reliable, and responsive questionnaires. Physical disability, in particular, has received considerable attention, and some techniques have been designed for a specific purpose whereas others have multipurpose applications.¹ Physical disability is one

Fig. 2.3 Homunculus for recording joint involvement by arthritis in routine clinical care.

of the two most important and immediate consequences of many musculoskeletal conditions. The capacity to measure this aspect of the disease, both in clinical trials and clinical practice, is paramount. Fully validated health status instruments including separate measures of pain and function are to be preferred over ad-hoc scales. Examples of disease-specific measures of function include the following:

- WOMAC Osteoarthritis Hip/Knee Index⁸
- AUSCAN Osteoarthritis Hand Index⁹
- Cochin hand index¹¹
- FIHOA¹⁰
- Bath Ankylosing Spondylitis Functional Index (BASFI)¹
- Fibromyalgia Impact Questionnaire (FIQ)¹

In contrast, measures such as the HAQ,⁵ AIMS,⁶ and AIMS2⁷ have multipurpose musculoskeletal applications and generic quality-of-life measures such as the Short Form-36 Health Survey (SF-36) and the European Health-Related Quality of Life (EuroQol) instrument can be used across a wide variety of diverse medical conditions.¹⁶ The SF-36 is available in different several formats. In recent years, there have been an increasing number of comparative studies of the performance of different health status measures. Different measures are underpinned by different constructs, vary in their responsiveness, and may impose different sample size requirements when used in clinical research applications.

The measurement of emotional disability in musculoskeletal disease is important because considerable psychological morbidity has been noted in patients with musculoskeletal disorders. There is a bidirectional inverse relationship between pain and emotional well-being. Furthermore, it is not surprising, given the degree of pain, disability, anxiety, depression, and diminished sense of well-being experienced by patients, that many musculoskeletal disorders have social consequences.

Participation/handicap

Measures of handicap reflect the social consequence of disease. Whether an individual is handicapped can be defined either by society or by an individual. The measurement of handicap in the rheumatic diseases has attracted relatively little attention. The Disease Repercussion Profile (DRP) is a valid and reliable measure of patient-perceived handicap. Relatively few interventional studies, even recent studies, include a measure of participation/handicap.

Global assessments

Global assessments by patient and physician of the patient's overall condition are commonly used in clinical trials and in clinical practice. It is extremely important to specify in the wording of the global question which aspects of the patient's condition are being considered (e.g., overall health status, symptom severity, disease activity, or an anatomic area). The patient global assessment is particularly important because it can be phrased to assess current status or change in symptom status and can be focused on a particular anatomic area, the condition in general, or the patient as a whole. Alternatively, it can be used to assess drug tolerability and/or efficacy or other aspects of the treatment program (palatability, compliance, affordability, convenience). The time frame over which the patient should consider his or her status should be defined (e.g., 48 hours, 1 week). It is debatable whether the physician global assessment of overall health adds much to the measurement process over and above the patient's own global assessment. However, the physician (or other assessor) can consider, in addition, aspects of the condition that are not assessable by the patient (e.g., radiographic change and biochemical, hematologic, and immunologic abnormalities) and may provide insight into whether the patient tends to amplify or minimize reported symptoms. Again, the physician requires clear specification as to which aspects of the condition should be considered when making his or her assessment. The time frame for the physician global assessment usually should be specified as "today" since the assessor generally has no knowledge of the patient's interval status other than that described by the patient and captured by the patient global assessment. At the present time there is no international consensus on the exact wording of the patient global assessment question or the preferred scaling format. However, a recent study has explored clinical benchmarking issues in RA, OA (hip/knee), OA (hand), AS, and low back pain using standardized patient global assessment questions developed through group consensus of expert opinion.¹⁷

Patients and physicians may differ in their perception of the patient's global assessment of disease activity or symptom severity. The determinants and consequences of this discrepancy need careful consideration, particularly by practitioners and researchers using interviewer-administered outcome questionnaires, in which there is potential for interaction between the interviewer and patient.

MULTIDIMENSIONAL HEALTH STATUS INSTRUMENTS

A large number of disease-specific and generic multidimensional health status measures have been developed. Many are very sophisticated instruments that have undergone extensive validation procedures and have high performance characteristics with superior levels of validity, reliability, and responsiveness. They are either self-administered or occasionally interviewer administered. It is very important for users to contact the originator before initial application to obtain instructions regarding usage (e.g., presentation, scoring, analysis), to procure an authentic current version of the instrument and a copy of the user's guide, and to obtain any required permissions. Many outcome measures are protected by copyright and/or trademark. The main reason for an originator to register copyright and trademark is to secure necessary protection for the measure, and this forms the basis for maintaining its integrity, authenticity, and appropriate usage.

Some health status measures have been developed in the form of segregated multidimensional indices that contain separate, distinct subscales exploring different aspects of the condition, such as HAQ, AIMS, AIMS2, WOMAC index, and AUSCAN index. They provide subscale scores on each of several separate dimensions. Others are in the form of aggregated multidimensional indices in which scores from several different dimensions are weighted and aggregated into a single score, such as the ICS, Pooled Index, and DAS. Health-related quality of life can be assessed either using a multi-item questionnaire, such as the SF-36 (and its derivatives), Nottingham Health Profile (NHP), or EuroQol, or using a utility-based methodology, for example the Health Utilities Index (HUI). A utility is a holistic measure of

the quality of life that rates an individual along a continuum from death (0.0) to full health (1.0). Models for predicting utilities from nonutility instrument data are evolutionary. For example, a model has been developed and validated to derive a utility score from WOMAC data that, at the group level, approximates the utility score estimated from the HUI in the same group of patients.¹ This provides an opportunity to derive utility scores from previously published studies that contain WOMAC data but that did not include a utility-based measure.

ASSESSMENT OF ADVERSE REACTIONS

Adverse reactions caused by treatment can result in symptoms, clinical signs, laboratory abnormalities, or death. Problems often arise in detecting, categorizing, attributing, and grading adverse events. Adverse event rates differ significantly depending on whether the assessment is based on open-ended questioning or structured questionnaires or is determined by a standard protocol. Various systems have been developed for categorizing adverse reactions to treatment. Attribution is the process of ascribing adverse reactions to interventions or other causes. The etiologic relationship is often graded as “none,” “possible,” “probable,” or “definite.” A number of factors determine the assigned level of the relationship, including prior knowledge of the patient, the pharmacodynamic profile of the intervention, and the duration of treatment. The most difficult attribution decisions are in assigning the grades of “none” versus “possible” and “probable” versus “definite” and in grading the intensity of an adverse reaction. Often severity is rated as being “mild,” “moderate,” or “severe.” A mild adverse reaction is one that is easily tolerated by the patient, causes minimal discomfort, and does not interfere with everyday activities. A moderate adverse effect is an adverse experience that causes sufficient discomfort to interfere with normal everyday activities, whereas a severe reaction is an adverse experience that is incapacitating and prevents normal everyday activities. Finally, it is important to categorize the outcome of an adverse reaction, for example, as “resolved,” “improved,” “unchanged,” “worsened,” “hospitalization required,” “hospitalization prolonged,” or “death.”

MEASUREMENT IN CLINICAL TRIALS

There are more than 100 different rheumatic disorders, each presenting a different challenge in outcome measurement. Regulatory authorities such as the U.S. Food and Drug Administration (FDA) and the European Medicines Agency as well as international nongovernment organizations such as the Osteoarthritis Research Society International (OARSI), OMERACT group, ACR, and Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) have pioneered the development of several evidence-based consensus-driven guidance documents. The FDA document on PROMs is particularly important in understanding the challenges of measuring patient-centered outcomes in regulatory environments.¹⁸ In addition to specifying domains and core set variables (measures) and identifying instruments, some organizations have also initiated investigations leading to the proposal of responder criteria, that is, criteria that could be used to stratify patients according to whether they have experienced a meaningful improvement with treatment. Although improvement with treatment is a very important goal, it is also important to determine the value of the final health state attained. Work in this area is, by comparison, relatively limited. However, several proposals have emerged that identify achievable, acceptable, or desirable health states. Finally, although there is a distinct paucity of general population-based normative values for PROMs, there has been some recent progress in this area.

There are a large and continually growing number of outcome measures to evaluate RA, OA, AS, reactive arthritis, systemic lupus erythematosus (SLE), low back pain, and fibromyalgia, as well as more generally applicable measures and measures of handicap, coping, helplessness, and quality of life. It is beyond the scope of this chapter to describe the development, validation, and scope of application of each of the currently available measures or the exact methods used to develop guidance documents or to develop and propose response and state-attainment criteria or normative values. Measurement preferences differ between different disorders, but pain, function, and patient global assessment are often emphasized. Where patient responses are captured and transmitted electronically, the FDA document *Guidance for Industry: Computerized Systems Used in Clinical Investigations* (2007) is relevant.¹⁹

Three areas that require special attention when considering data capture on a global scale are short-forms, alternate-language translations, and electronic data capture. Concerns regarding respondent burden in completing

PROMs has stimulated the development of shortened versions of existing measures. Although time to completion may be reduced, short-forming also reduces content validity. When short-forming is replicated in different cultures and interventional environments it is noted that the short forms differ. For example, in the case of proposed short forms of the WOMAC index, no two short forms are the same but each of the 24 items is included in at least one of the proposed short forms.²⁰ The creation of alternate-language translations of PROMs requires skill, experience, and close attention to the standard operating procedures necessary to create linguistically valid and culturally appropriate translations.²¹ The process should be conducted only in association with the originator of the measure. Users should clearly differentiate between alternate-language translations created to a commercial standard and those resulting from ad-hoc processes.²⁰ Electronic data capture is gradually replacing traditional paper-based capture of patient responses to PROMs. The development of electronic forms of existing measures may require modifications to language and format. The extent to which further linguistic and clinimetric validation are required is unclear at present. As with alternate-language creation, the development of electronic versions should be undertaken only by entities with the required special skills and experience and should adhere to standard operating procedures and be conducted only in association with the originator of the measure.²⁰

Rheumatoid arthritis

In general, RA clinical trials evaluate either fast-acting, symptom-modifying drugs, such as nonsteroidal antiinflammatory drugs and analgesics, or slow-acting disease-modifying antirheumatic drugs, which include the biologic agents. Several valid, reliable, and responsive outcome measures have been developed for the evaluation of patients with RA. In addition, ICF core sets have been specified for RA and validated from a patient perspective, and commonly used instruments have been mapped to the framework. Normative data for the HAQ have been published and minimum clinically important improvement (MCII) and patient-acceptable symptom state (PASS) estimates explored for RA (Box 2.2). The following recommendations, developed by the OMERACT group and ratified by the ACR,¹ currently

BOX 2.2 PROPOSED STATE-ATTAINMENT CRITERIA FOR ARTHRITIS AND MUSCULOSKELETAL CONDITIONS

Patient-Acceptable Symptom Severity (PASS75) (preliminary estimates based on REFLECT study¹) (all values on 0-100 scales)

Osteoarthritis (hip and knee)

WOMAC Pain = 39.3; WOMAC Stiffness = 44.8; WOMAC Function = 47.7; PGA = 47.1.

Osteoarthritis (hand)

AUSCAN Pain = 41.0; AUSCAN Stiffness = 37.8; AUSCAN Function = 44.8; PGA = 41.6.

Rheumatoid arthritis

Pain = 40.7; HAQ = 39.4; PGA = 41.6.

Ankylosing spondylitis

Pain = 40.6; PGA = 43.2; BASFI = 40.4; BASDAI = 38.9; PGA = 43.2.

Low back pain

Pain = 39.4; Roland Morris Disability Questionnaire = 30.7; PGA = 40.3.

Bellamy et al³³: Low-Intensity Symptom State-Attainment (BLISS) Index Osteoarthritis (knee)

Two components—symptom level based on the WOMAC Osteoarthritis Index (pain, stiffness, function, and total score) and time combined in a state-attainment-based analysis.

Magnitude (normalized units [nu] 0-100 scale):

≤25 nu, ≤20 nu, ≤15 nu, ≤10 nu, ≤5 nu

Time to first BLISS day:

BLISS days over 12 months

Patients in BLISS at month 12

Patients in BLISS at any time

BLISS maintained to month 12

Number of BLISS periods over 12 months

AUSCAN, Australian-Canadian Hand Osteoarthritis Index; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BLISS, Bellamy Low-Intensity Symptom State-Attainment Index; HAQ, Health Assessment Questionnaire; PGA, patient global assessment; WOMAC, Western Ontario and McMaster Osteoarthritis Index.

comprise the ACR minimum core set for RA clinical trials: pain, physical function, number of swollen joints, number of tender joints, patient global assessment, investigator global assessment, erythrocyte sedimentation rate or C-reactive protein level, and imaging. Individual response criteria based on these clinical variables and referred to as the ACR20¹ have been proposed as follows: 20% or more improvement in tender and swollen joint counts and 20% or more improvement in scores on three of the five remaining ACR core set measures. These are particularly relevant for evaluating the response to symptom-modifying drugs. The sufficiency of the ACR20 criteria has been considered, and higher-level response requirements based on the ACR50 and ACR70 criteria evaluated.¹ Compared with ACR20/50/70 criteria, cut points of 50/70/85 for the Simplified Disease Activity Index (SDAI) and the Clinical Disease Activity Index (CDAI) define minor, moderate, and major responses.²²

The treat-to-target approach to management, which characterizes the ACR²³ and EULAR²⁴ recommendations for the management of RA, has stimulated further consideration of the definition of remission in RA. Definitions of remission and minimum disease activity have been proposed based on several outcome measures, including the DAS28, ACR/EULAR remission criteria, SDAI, and CDAI.²⁵⁻²⁷ Remission rates are instrument and cut-score dependent. Thus, in a comparative study in early RA, higher remission rates were observed when DAS28 criteria were used than when ACR/EULAR criteria were employed.²⁸

Osteoarthritis

Clinical trials in OA can be subdivided into those that assess symptom-modifying OA drug effects and those that assess structure-modifying drug effects. Several valid, reliable, and responsive outcome measures have been developed for the evaluation of patients with OA of the hip, knee, and hand. ICF core sets for OA have been elaborated and the WOMAC index, ICS, and Osteoarthritis Knee and Hip Quality of Life (OAKHQOL) questionnaire mapped to the ICF core set. A unique set of age- and gender-specific general population-based normative data have been reported for the WOMAC and AUSCAN index subscales (Figs. 2.4 and 2.5)^{29,30} and MCII and PASS estimates explored for OA based on the WOMAC index for hip and knee OA and the AUSCAN index for hand OA (see Box 2.2). MCII and PASS estimates may vary across instruments, subscales, countries, and therapeutic environments.³¹ Although there are no clinical measures specific for structure-modifying drug trials in OA, it is of note that the WOMAC index detected clinical benefits associated with structural conservation in a recent double-blind, randomized, controlled clinical trial of strontium ranelate.³²

Core set measures for OA have been proposed by the OMERACT group and ratified, or in the case of hand OA, developed by the OARSI.¹ OMERACT and OARSI core set measures for future phase 3 studies in hip, knee, and hand OA are pain, function, patient global assessment, and, for studies of 1 year or longer, joint imaging using validated methods and standardized techniques. OMERACT and OARSI have jointly proposed responder criteria

for hip and knee OA, based on combinations of absolute and percentage changes in pain, function, and patient global assessment.¹ The OMERACT-OARSI responder criteria are applicable to both hip and knee OA patients and are not intervention class specific. Response criteria developed for OA and proposed by other groups include definitions of minimum perceptible clinical improvement, minimum clinically important difference, MCII, WOMAC 20-50-70, and AUSCAN 20-50-70. In addition to these definitions based on the degree of change, other definitions have been proposed based on the health state attained, the so-called state-attainment criteria. Definitions based on PASS and the Bellamy Low-Intensity Symptom State-Attainment (BLISS) Index (see Box 2.2)³³ are examples of initial attempts to establish working definitions for use in clinical practice and clinical research. Observations that statistically significant between-group differences are detectable at low or very low symptom intensity levels, so-called BLISS states, are of particular importance in the evaluation of therapeutic interventions³³ because they provide indicators of achievable health states (see Box 2.2). Although further research is necessary, observations of BLISS states have been made with the WOMAC and AUSCAN indices and in different classes of interventions and confirm that such states are achievable by some, but not all, patients. Attempts by the OARSI to develop a surrogate indicator for total joint replacement in hip and knee OA has not, to date, resulted in cut scores for pain and function capable of discriminating between patients who are and who are not considered candidates for total joint replacement by their orthopedic surgeons.^{34,35}

Ankylosing spondylitis

Several valid, reliable, and responsive outcome measures have been developed for the evaluation of symptom severity and disease status in patients with AS.³⁶ Clinical measurement in AS encompasses both the peripheral joints and extraarticular involvement, as well as axial skeletal involvement. Through the OMERACT process and the Assessment in Ankylosing Spondylitis (ASAS) Working Group, core set measures have been identified for use in different clinical research settings.¹ The ASAS group has also developed a definition of short-term improvement (ASAS20) based on four domains: physical function, pain, patient global assessment, and inflammation. ASAS20 defines improvement as 20% or more and 1 unit or more (0 to 10 scale) improvement in at least three of the four domains, with no worsening (defined as deterioration of 20% or more and 1 unit or more [0 to 10 scale]) on the fourth dimension.¹ The recent emergence from the ASAS/OMERACT initiative of the Ankylosing Spondylitis Disease Activity Score (ASDAS), based on the weighted sum of measures of back pain, morning stiffness, patient global assessment, peripheral joint pain/swelling, and either C-reactive protein level or erythrocyte sedimentation rate, provides a composite index for evaluating disease activity in AS.³⁷

The BASFI, Dougados Functional Index (DFI), Health Assessment Questionnaire for the Spondyloarthropathies (HAQ-S), and Revised Leeds Disability Questionnaire (RLDQ) instruments have been mapped to the ICF

Fig. 2.4 Age- and gender-specific normative values for the Western Ontario and McMaster (WOMAC) Osteoarthritis Index Physical Function subscale based on a random sample of the general population ($n = 7336$). (From Bellamy N, Wilson C, Hendrikz J. Population-based normative values for the Western Ontario and McMaster (WOMAC) Osteoarthritis Index: part I. *Sem Arthritis Rheum* 2011;41:139-48, with permission.)

Fig. 2.5 Age- and gender-specific normative values for the Australian-Canadian (AUSCAN) Hand Osteoarthritis Index Physical Function subscale based on a random sample of the general population ($n = 7231$). (From Bellamy N, Wilson C, Hendrikz J. Population-based normative values for the Australian/Canadian (AUSCAN) Hand Osteoarthritis Index: part 2. *Semin Arthritis Rheum* 2011;41:149-56, with permission.)

framework, and MCII and PASS estimates have been explored for AS (see Box 2.2). PASS estimates for the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and BASFI have differed for observations made on patients with AS in different countries.^{38,39}

Psoriatic arthritis

Outcome measurement in psoriatic arthritis (PsA) has undergone considerable refinement in recent years, and there are now available several instruments for evaluating different aspects of the condition.⁴⁰ Both single-domain and composite measures have been developed; the former assess only a single aspect of the condition, whereas the latter encompass more complex issues such as quality of life and disease activity.^{40,41} Consensus has been reached on core set domains for randomized controlled trials and longitudinal observational studies in PsA, namely, peripheral joint activity, skin activity, patient global assessment, pain, physical function, and health-related quality of life. In preparation for treat-to-target approaches to PsA management, a minimal disease activity definition has been proposed.⁴² Some progress has been made toward the development of response definitions for PsA-relevant outcome measures.⁴¹⁻⁴³ In mapping standard measures of functioning to the ICF framework, it has been noted that several areas of concern to patients with PsA are inadequately covered.⁴⁴

Systemic lupus erythematosus

There are several validated instruments for conducting outcome measurement in patients with SLE. Modifications of some of those measures, in particular, the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), Lupus Activity Index (LAI), and Systemic Lupus Activity Measure (SLAM), have been proposed for use in SLE in pregnancy. These modifications are referred to respectively as SLEPDAI, LAI-P, and m-SLAM.

Core set domains for clinical trials and longitudinal studies have been proposed by the OMERACT group and include (1) disease activity, (2) health-related quality of life, (3) organ damage, and (4) toxicity/adverse events. The ACR has proposed response criteria for SLE clinical trials.¹ These criteria are based on absolute change, are instrument specific, and have been proposed for the British Isles Lupus Assessment Group (BILAG), SLEDAI, SLAM, European Consensus Lupus Activity Measurement (ECLAM), Safety of Estrogens in Lupus Erythematosus National Assessment Modification of SLEDAI (SELENA-SLEDAI), and Responder Index for Lupus Erythematosus (RIFLE) instruments. The criteria are in the form of threshold values for improvement and worsening. The Pediatric Rheumatology International Trials Organization and the ACR have proposed provisional response criteria for juvenile SLE based on at least 50% improvement in any two of five core set measures and with no more than one of the remaining measures worsening by more than 30%.¹ Most recently a valid and reliable responder index based on the SLEDAI-2000 has been proposed and assesses 50% or more improvement in lupus disease activity.^{45,46}

Definitions of “active disease” and minimal clinically meaningful change for the SLEDAI-2000 have also been published.⁴⁷

Systemic sclerosis

In reviewing outcome measures for clinical trials in systemic sclerosis, the OMERACT group considered that the HAQ and Scleroderma Health Assessment Questionnaire (SHAQ) were the only two patient-centered measures ready for use in clinical trials. Although the measurement of disease activity in systemic sclerosis remains challenging, the European Scleroderma Study Group has proposed preliminary activity criteria based on the summation of scores across multiple variables. In addition, estimates of minimal clinically important difference for several patient-centered outcome measures (Health Assessment Questionnaire Disability Index [HAQ-DI], fatigue, pain, sleep, patient global assessment, SF-36) have been developed based on a clinical practice setting.⁴⁸

Behçet disease

There is a paucity of measurement tools to assess disease activity and condition-specific quality of life in Behçet disease. The development and validation of the Behçet's Disease Activity Index (BDAI)¹ and the Behçet's Disease Quality of Life (BD-QoL) index¹ therefore represent important contributions to outcome measurement in Behçet disease.

Sjögren syndrome

Core set measures for Sjögren syndrome were proposed several years ago: sicca symptoms, sicca objective (oral), sicca objective (ocular), health-related quality of life, laboratory measures, and fatigue. Subsequently two indices, the Sjögren's Syndrome Disease Damage Index (SSDDI) and the Sjögren's Syndrome Disease Activity Index (SSDAI), were proposed.¹ Most recently the EULAR Sjögren's Task Force has developed two new indices, one to assess symptoms (EULAR Sjögren's Syndrome Patient Reported Index [ESSPRI]), and the other to assess disease activity (EULAR Sjögren's Syndrome Disease Activity Index [ESSDAI]).^{49,50} Although both indices require further validation, they create novel measurement opportunities since they are based respectively on patient⁴⁹ and expert⁵⁰ opinion.

Polymyalgia rheumatica

Core set measures for polymyalgia rheumatica proposed by the European Collaborating Polymyalgia Rheumatica Group include five measures: pain, physician global assessment, morning stiffness, C-reactive protein level, and ability to elevate the upper limbs. A recent multinational collaborative evaluation of outcome measures in polymyalgia rheumatica has concluded that patient-reported global pain, hip pain, morning stiffness, physical function (Modified Health Assessment Questionnaire [MHAQ]), mental

function and an inflammatory marker are the best measures of disease activity and treatment response.⁵¹

Inflammatory myopathies

The International Myositis Assessment and Clinical Studies group has proposed three tools for the evaluation of patients with idiopathic inflammatory myopathies. These tools are the Myositis Intention to Treat Activity Index (MITAX), Myositis Disease Activity Assessment Visual Analogue Scales (MYOACT), and Myositis Damage Index (MDI). The interrater reliability and construct validity of the MDI were confirmed in a recent evaluation.⁵² Preliminary consensus-based estimates of clinically important improvement in adult and juvenile idiopathic inflammatory myopathies have been proposed as follows: muscle strength and physical function, 15%+; physician and patient global assessment, 20%+; and serum levels of muscle-associated enzymes, 30%+. The Pediatric Rheumatology International Trials Organization and the ACR have proposed core set measures for juvenile dermatomyositis that include physician global assessment of disease activity, muscle strength, global disease activity measure, parent's global assessment of patient's well-being, functional ability, and health-related quality of life.

Vasculitis

Outcome assessment in the different pathologic entities that collectively form the vasculitides is challenging. Different conditions may require different indices and multidimensional measures to capture the impact of pathologic processes affecting different organs and structures. Attempts to develop a multisystem measure include the Combined Damage Assessment (CDA) Index for vasculitides involving small- and medium-sized vessels, Vasculitis Damage Index (VDI), and Birmingham Vasculitis Activity Score/Wegener's Granulomatosis (BVAS/WG) for evaluating patients with Wegener's granulomatosis. The reliability, construct, and discriminant validity of the BVAS/WG have been assessed and the index proposed for use in clinical investigation. In a recent comparative study, although the CDA and VDI were both reliable, the CDA was considered more complex and less practical than the VDI.⁵³ Since its inception, the BVAS has undergone revision, and version 3 has been validated for use in systemic vasculitis.^{54,55} The OMERACT group has established core set domains for clinical trials of antinuclear cytoplasmic antibody-associated vasculitis: namely, disease activity, damage assessment, PROMs, and mortality.⁵⁶

Osteoporosis

The main focus of osteoporosis studies is bone loss and fracture prevention. Core set measures for bone loss prevention studies (bone mineral density measured at two sites, biochemical markers) and fracture prevention studies (fracture; hip, knee, and spine bone mineral density; biochemical markers; change in height) in osteoporosis have been proposed by the OMERACT group. In addition, ICF core sets have been suggested for osteoporosis and the content of osteoporosis-targeted health status measures compared using the ICF framework. There are currently several condition-specific quality-of-life measures for osteoporosis, which differ in their content, format, and method of administration.⁵⁷

Low back pain

Outcomes in patients with low back pain can be assessed with various instruments as well as with quality-of-life measures. The OMERACT group has proposed preliminary response criteria (Therapeutic Responder Index [TRI]) for chronic low back pain, based on at least 30% improvements in pain and in patient global assessment and no worsening in function.¹ A further evaluation of the TRI suggests that it is particularly sensitive to the cutoff point used for improvement in the patient global assessment component.⁵⁸ MCII and PASS estimates have been explored for low back pain based on the Roland Morris Disability Questionnaire.

Fibromyalgia

The OMERACT group has developed core set domains for fibromyalgia: namely, pain, tenderness, fatigue, patient global assessment, multidimensional function, and sleep disturbance.⁵⁹ Various outcome measures have been used in fibromyalgia clinical trials.⁶⁰ An evaluation of outcome measurement performance has suggested that existing instruments adequately measure core OMERACT domains for fibromyalgia.⁶⁰ Development of a fibromyalgia responder index and disease activity score is considered both feasible and a priority.⁶⁰ Recently two responder definitions have been

proposed, both including 30% or more reduction in pain and 10% or more improvement in physical function.⁶¹ In addition, the reliability, validity, and responsiveness of the Combined Index of Severity of Fibromyalgia (ICAF) have been confirmed.⁶²

OUTCOME MEASUREMENT IN ROUTINE CLINICAL PRACTICE

For many rheumatologists in routine practice, the goal is to track efficiently the progress of individual patients, even if there is no investigational goal. In addition to the reliability, validity, and responsiveness of the measure, practitioners also value attributes such as simplicity, rapid completion, and easy scoring.⁶³

The major emphasis in musculoskeletal clinical metrology has been on the development of instruments for clinical research rather than for routine clinical purposes. The challenge now is to apply these techniques in clinical practice, in which feasibility issues become paramount (Box 2.3).

Combinations of disease-specific, generic health-related quality-of-life and global measures are particularly useful in clinical practice. Six issues of practical importance deserve special consideration:

1. Although measures of discomfort (pain), disability (function), and patient and physician global assessment are common to all rheumatic diseases, conditions with extraarticular consequences may require additional organ-specific assessments (e.g., skin scores in scleroderma).
2. Outcome measurement in children can be challenging. It is important to select scales that are valid, reliable, responsive, age-appropriate, and comprehensible in this particular group of patients.
3. In addition to defining a priori a schedule for assessing the beneficial effects of a treatment program, establishing a schedule of monitoring for adverse events, particularly for pharmacologic interventions, is equally important. Such a schedule should be capable of detecting both clinical and nonclinical (laboratory) forms of toxicity in a timely fashion.
4. Methods for handling data are important. For paper-based applications, flowcharts are particularly useful in documenting longitudinal change in clinical status as well as for charting the nonclinical (laboratory) tolerability of antirheumatic drugs. Expanding opportunities for electronic data capture are progressively solving many of the current problems with collection, storage, and analysis of quantitative data. Electronic data capture can be achieved on a variety of platforms including desktop and laptop computers, personal digital assistants, Web-based applications, and mobile telephones. Mobile telephones in particular deserve special attention because they are ubiquitous and provide opportunity for bidirectional or even multidirectional communication between patients and their health care provider(s). It should be noted that electronic data capture using mobile (cellular) phones is acceptable to patients; produces valid, reliable, and responsive data showing high levels of correlation with paper-based counterparts; can be achieved remotely, independently, and repeatedly; is able to transmit data over long distances directly into a host server

BOX 2.3 REQUIREMENTS OF AN OUTCOME MEASURE FOR CLINICAL PRACTICE APPLICATION

Clinimetric requirements

- Validity, reliability, responsiveness

Feasibility requirements

- Ease of administration, quick to complete, affordable, low burden on health care recipient and health care providers, provides information contemporaneous with patient provided interaction, aligned with other aspects of clinical record keeping

Relevance requirements

- Provides clinically relevant information that can underpin shared goal setting and decision-making

Interpretation requirements

- Provides observations that can be contemporaneously benchmarked against relevant prior assessments and can be indexed against appropriate response, state-attainment criteria, and normative benchmarks

for instant archiving; and can be conducted with a variety of commonly available mobile (cellular) phones.⁶⁴⁻⁶⁶

5. The concomitant use of disease-specific patient and physician global assessments and generic health-related quality-of-life measures provides a particularly powerful combination. In inflammatory polyarthritis these measures can readily be supplemented by an articular index in the form of a simple count of tender and swollen joints.
6. The development of responder criteria, state-attainment criteria, and normative data is an important step in the transfer of measurement procedures used in research environments into routine clinical practice. They permit clinical benchmarking and thereby facilitate data interpretation. Some of the proposed benchmarks should permit more effective monitoring of patient progress and response to treatment (Fig. 2.6).

Implementation of what might be termed *quantitative rheumatology* may require the development of new instruments or modifications to existing instruments, measurement and data-handling processes, and analysis, interpretation, and communication procedures to meet the demands of routine clinical practice. However, there is no reason to delay using some of the shorter, user-friendly, patient self-administered questionnaires and emerging technologies currently available. The ability to quantitate the clinical condition provides patients, medical practitioners, allied health professionals, third-party payers, and litigators with much important and useful information. Furthermore, proposed definitions of response and state attainment, the elaboration of general population-based normative values, and innovations in electronic data capture all contribute to an expanding capability to collect and interpret health status information in a manner capable of informing shared decision-making and goal setting in clinical practice, and the evaluation of new interventions and therapeutic strategies in clinical research.

Fig. 2.6 Response to treatment in osteoarthritis (OA) can be monitored over an extended period by a combination of responder and state-attainment criteria. Principles of health economics and application to rheumatic disorders

■ JOHN B. WONG

- Economic analyses in medicine include cost, cost-benefit, cost-effectiveness, and cost-utility analysis.
- The most commonly used method in health care is cost-utility analysis, often for health technology assessment to determine the most efficient use of resources.
- Beyond cost-effective use of resources, however, equity issues and budget impact analyses affect policymaker decisions.
- For physicians, these economic analyses can help inform cost-effective care, such as in the management of rheumatoid arthritis and osteoarthritis and the assessment of the risk of fragility fractures in osteoporosis.

INTRODUCTION

Excellence in the art of medicine involves making optimal decisions. Physicians make implicit or explicit choices to treat, to test, or to do neither to each patient based on that patient's unique circumstances. They also consider the safety, efficacy, adverse effects, and indications for medications, and the sensitivity, specificity, harms, and indications for diagnostic and prognostic tests. With the recent growth in novel drugs, medical devices, tests, and imaging modalities, health care costs have risen substantially worldwide, so increasingly, physicians recognize that they should incorporate economic considerations into their medical decision-making. Besides efficacy as determined by randomized controlled trials and effectiveness as determined by observational studies, physicians increasingly must also be knowledgeable about costs.

Simply considering costs, however, does not provide a measure of value or the health benefit attained; that is, does the intervention provide an efficient use of societal resources? Driven in part by advances in health care technology, such as biologic treatments for rheumatoid arthritis (RA),¹ medical care costs account for a growing proportion of each country's gross domestic product.^{2,3} Economists consider the *opportunity costs* of those expenditures; that is, would society have gained greater benefit from spending some of those health care dollars instead on education, social welfare, environment, defense, or an alternative societal investment?² The same thinking applies to societal benefits of spending on rheumatic disorders as opposed to other conditions. Thus health economics seeks to determine the optimal use of societal resources by assessing the value obtained from alternative uses for those resources.

This chapter discusses the basic concepts of economic analysis including cost-effectiveness analysis for health technology assessment followed by applications of these principles in rheumatology.

CONCEPTS OF HEALTH ECONOMIC ANALYSIS

Types of costs

Costs are usefully divided into four main types, which are described in [Box 3.1](#).

Perspectives

Economic analyses may be done from a variety of perspectives, which then affects the types of costs considered and the time frame of the analysis. These perspectives are listed in [Table 3.1](#).^{4-6,8}

Types of economic analysis

Cost analysis

Cost analysis (also called *cost minimization*, *cost identification*, or *cost consequence*) measures the economic burden incurred by a disease or treatment.^{6,9} Typical costs include direct medical and health care costs, costs associated with adverse effects, savings from prevention or alleviation of disease, and possibly costs of additional disease from prolonged life expectancy, but these costs may vary depending on the analytic perspective and time frame.³ In cost analysis, alternative strategies are demonstrated or assumed to be equivalent, so this kind of analysis provides no measure of the resulting health outcomes and simply identifies the optimal strategy by determining the "cheapest." Because alternative health interventions rarely have the same effectiveness, cost analysis is an uncommon health economic analysis.

Cost-benefit analysis

In cost-benefit analysis, all costs and health benefit outcomes are expressed in terms of a single monetary attribute, for example, dollars.^{3-6,9} Costs are determined as with cost minimization, but in addition health benefits are translated into a monetary amount. Thus cost-benefit analysis provides a measure of absolute economic cost and absolute economic benefit. Each strategy is compared with current practice, so cost-benefit analysis results may be expressed as a ratio of costs to benefits or more preferably summed to yield the *net present value*. If the net present value is positive, then savings from benefits exceed the cost of expenditures, so policymakers could simply pick those strategies with the highest net present value when choosing which programs to fund. Although many applied economists view cost-benefit analysis as the gold standard,¹⁰ it is not as well accepted in health care because of difficulties associated with placing a monetary value on health benefits, that is, human life outcomes.

Cost-effectiveness analysis

To avoid the difficulties associated with placing a monetary value on human life, cost-effectiveness analysis (or a subset called *cost-utility analysis*) has become the most prevalent form of economic analysis in health care. Costs continue to be expressed in the same unit, but benefits are expressed as a meaningful clinical outcome (e.g., satisfaction of the American College of Rheumatology 20% improvement criteria [ACR20]).^{5,6,9} In cost-effectiveness analysis, dividing the cost of the intervention by its effectiveness yields the *average cost-effectiveness ratio*.¹¹ However, for technology assessment, the average cost-effectiveness ratio can be misleading (see RA example later), so the preferred outcome measure is the *incremental cost-effectiveness ratio* (ICER; also called *marginal cost-effectiveness ratio*) comparing two alternative strategies ([Fig. 3.1](#)).^{6,9,11} It divides the additional cost of the new intervention by its additional clinically meaningful benefit, which results in one of four possible outcomes (see [Fig. 3.1](#)): (1) higher costs and lower effectiveness when the new strategy is *dominated* or *inferior*; (2) lower costs and higher effectiveness when the new strategy is *dominant* or *cost saving*; (3) lower costs and lower effectiveness (rare); and (4) higher costs and higher effectiveness. For the last two situations, an ICER can be calculated, for example, the incremental cost to obtain one more ACR20 response.

Policymakers should not adopt new strategies that are dominated but should adopt those that are cost saving. Typically, however, if something is more effective, then it usually costs more; so among these more common strategies, policymakers could then choose to fund those interventions that fall below an acceptable range called the societal *willingness to pay*; that is, those that supply sufficient value for which the benefit is judged to be worth the additional cost. For example, an ICER of \$1 to achieve an additional ACR20 may be acceptable, but \$1 million to achieve one additional ACR20 may not be.

BOX 3.1 TYPES OF HEALTH COSTS

- **Direct medical costs** include resources required to provide care such as hospitalizations, procedures, surgeries, outpatient office visits, rehabilitative and nursing home care, care by physician and allied health professionals, medications, devices, equipment, supplies, and tests.⁴⁻⁶
- **Direct nonmedical costs** reflect out-of-pocket patient costs and include the following:
 - *Patient time costs* for the time spent seeking or participating in care
 - *Marketed care giving* for out-of-pocket cost to receive family care
 - *Unmarketed care giving* for informal care giving
 - *Transportation and nonmedical services* for travel, lodging, home aids, or special food, and clothing
- **Productivity costs** are time costs frequently called *indirect costs* and refer to loss of employment due to morbidity (disability, absenteeism, reduced productivity while working) or mortality (reduction in life expectancy).^{4,6} For example, the families of children with juvenile rheumatoid arthritis spent 5% of their income on out-of-pocket medical and nonmedical costs and lost salary.⁷
- **Intangible costs** include pain, suffering, and fear for the illness or its treatment.⁵⁻⁶

TABLE 3.1**Perspectives of health costs**

Perspective	Includes
Patient	Direct nonmedical costs not covered by insurance, such as any copayments for drugs, over-the-counter medications, devices, office visits, and indirect costs
Hospital	Direct and direct nonmedical costs during a hospitalization
Payer	Excludes patient out-of-pocket costs and indirect costs
Societal	Direct medical, direct nonmedical, and indirect costs and a lifetime time frame

Fig. 3.1 The incremental cost-effectiveness ratio (ICER) describes the additional cost and the additional benefit obtained from a new intervention compared with standard of care. When the net cost and net benefit are considered, the new intervention may cost more or less and may yield more benefit or less, thereby yielding differences that fall into one of four quadrants. Dividing the net cost by the net benefit yields the cost to achieve one additional benefit (the ICER).

Cost-utility analysis

To avoid the difficulties associated with comparing alternative effectiveness measures in cost-effectiveness analyses—for example, cost to achieve an ACR20 response versus cost to avoid a myocardial infarction—cost-utility analysis uses a standardized effectiveness measure, namely length and quality of life, usually expressed as quality-adjusted life-years (QALYs). In

INCREMENTAL COST-EFFECTIVENESS RATIOS FOR TREATMENTS

Fig. 3.2 Published incremental cost-effectiveness ratios (ICERs). The graph displays published incremental cost-effectiveness ratios for five interventions: colon cancer (CA) screening with colonoscopy, highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infection, intense treatment (Rx) for diabetes mellitus, hemodialysis for end-stage renal disease, and testing of metastatic breast cancer patients for tumor HER2 protein overexpression or gene amplification and treatment with trastuzumab when results are positive. Lower ICERs indicate more efficient use of resources; that is, more “bang for the buck.”

such a case, the incremental cost-effectiveness of coronary stenting for myocardial infarction could be compared with that of biologic therapy for RA because both would be expressed as cost per QALY gained (the additional cost to increase life expectancy by one QALY). Approving or funding those interventions that are cost-saving or those that have the lowest ICER would provide society with the greatest benefit for a given expenditure. A league table illustrates how a policymaker might use such information to determine value and funding priorities.¹²⁻¹⁶ For example, if a payer had \$1 million to spend, spending that amount on colon cancer screening would yield 66 QALYs (\$1 million ÷ \$15,100 per QALY gained) for the population as opposed to 8 QALYs (\$1 million ÷ \$125,000 per QALY gained) with HER2 testing and treatment with trastuzumab, a monoclonal antibody for breast cancer (Fig. 3.2).^{12,16}

Quality of life

Of particular relevance in rheumatology, patients, physicians, and policymakers increasingly recognize the importance of quality of life to account for disease morbidity, in addition to length of life. Quality of life is typically scaled from 1 for perfect health to 0 for death, so individuals with morbidity receive only partial credit for each year that they are alive.¹⁷ For example, if the quality-of-life adjustment factor is 0.4 for severe disability, patients with severe disability who live for 10 years receive credit for living 4 quality-adjusted years, so a treatment that prevents this severe disability potentially increases QALYs by 6 years. For diseases with a low quality of life, interventions that prevent or restore quality of life then have more opportunity to provide economic value by adding “life” to years instead of adding years to life. Thus, in cost-utility analysis, the outcome measure is the incremental cost to increase life expectancy by one “QALY gained,” which is equivalent to increasing life expectancy by 1 year of perfect health.

Time horizon and discounting

The time horizon for the economic analysis refers to the time period under consideration, which may range from short, for example during hospitalization, to lifelong or lifetime (or in between) depending on the perspective. When longer time horizons are examined, present costs are typically more valuable than future ones, not simply because of inflation but also because present expenditures could alternatively be invested productively to yield a larger future amount.

For example, given a choice between being given \$100 now or \$100 a year from now, most individuals would prefer to receive that money now.¹⁷ Hence, the \$100 a year from now is worth less now; it has a lower *discounted* present value. How much less depends on the annual discount rate, which varies by country. In the United Kingdom, the rate is 3.5%, and in the United States it is 3%,¹⁷ so \$100 a year from now has a present-day worth of \$97.09 in the United States and \$96.62 in the United Kingdom.

Reflecting the higher present value of money, discounting is consistent with health care policies hoping to minimize current fiscal year drug budgets and is particularly relevant for preventive treatments because treatment occurs now and disease complications occur in the future. For example, the cost of biologic therapies for patients with RA occurs now, but disability or expensive joint replacement costs occur in the future. When a 3% annual discount rate is used, spending \$10,000 this year would be comparable to spending only \$7441 in 10 years and \$5537 in 20 years.⁵ Similarly, because costs are discounted, health benefits are also discounted, so future health benefits are valued less than benefits that would accrue now (Box 3.2).

Reference case

To reduce methodologic variability in economic evaluations, the U.S. Panel on Cost-Effectiveness Analysis in Health and Medicine in 1996 established a *reference case* set of minimum standards that included the societal perspective, reasonably long time horizons, ICERs, QALYs, discounting, and sensitivity analyses to assess the robustness of the results.^{4,8} Within rheumatology, the Outcome Measures in Rheumatology Clinical Trials (OMERACT) group has proposed additional methodologic guidance.¹⁸⁻²²

Health technology assessment

Over the past 20 years, health technology assessment (Fig. 3.3) to inform health policy and clinical decision making has grown worldwide as a multidisciplinary systematic approach to assess the introduction of, access to, and diffusion of innovative health technologies, including medications, devices, diagnostics, and treatments. As one example, the United Kingdom's National Institute for Health and Care Excellence (NICE) bases national funding or reimbursement recommendations regarding new and existing medicines on a review of clinical and economic evidence. The evaluation of clinical evidence assesses how well the drug works, and the evaluation of the economic evidence determines how well the drug works relative to its costs, or, succinctly, whether the drug provides sufficient value for its cost.

BOX 3.2 KEY MESSAGE

The incremental cost per quality-adjusted life-year gained can be considered to be equivalent to the present cost (in current year or year in which the analysis was performed) to increase life expectancy by a year of perfect health in that same analysis year.

NICE recognizes an evidence hierarchy with a preference for direct head-to-head randomized controlled trial efficacy studies and indirect comparisons as a second choice. However, because NICE also appreciates the limitations of such efficacy studies—namely, selected populations, short-time spans, and limited comparators—it also acknowledges the need to supplement efficacy studies with good-quality observational or effectiveness studies. The economic evidence considers a societal perspective and a lifetime time horizon to account for future benefits and economic savings or expense. Because randomized trials have limited follow-up, achieving the lifetime time horizon involves computer simulation modeling of the relevant disease and treatments including mortality as might occur from the disease or treatment in addition to that in an age-, sex-, and race-matched general population with morbidity from the disease or treatment represented by quality-of-life adjustments, and societal costs.

Decision analysis modeling

Despite rigorous systematic reviews of efficacy and effectiveness of health care interventions, patients, providers, and policymakers may remain in doubt about what they should do because of uncertainty, tradeoffs, and values. First, residual uncertainty may remain regarding meaningful patient-relevant outcomes because of reliance on surrogate outcome measures or limited follow-up time or use of subgroups with an inadequate sample or restrictive inclusion and exclusion criteria during the randomized controlled trials. Second, treatment decisions often involve tradeoffs. Treatment benefits may occur, but harms may also ensue. Thus optimal decision-making for individuals may depend on their values (or preferences) regarding the outcomes, and those values and preferences may vary widely in a population. Decision and cost-effectiveness analyses typically invoke a prescriptive, normative approach to decision-making in the face of uncertainty by explicitly structuring decisions into (1) choices (alternative treatment strategies), (2) chances (the likelihood of outcomes resulting from the choices), and (3) consequences (valuation of the outcomes in terms of mortality, morbidity, and costs). The decision models then calculate the costs and utility of each treatment and the difference between the alternatives as an extension (or decline) in life expectancy or quality (morbidity)—adjusted life expectancy and increase or decrease in costs.

The most commonly used computer simulation model is a Markov or Monte Carlo simulation, in which a predefined and mutually exclusive set of health states represent the natural history of disease.²³ The patient cohort starts the simulation in a health state such as Well or a set of health states (e.g., some Well and others Sick). Time is divided into ticks of the clock represented by Markov cycles of a specified duration (e.g., 1 year). Over time, patients move among these health states; some may die, become sick, or maintain their same state of health. The simulation continues until all

Fig. 3.3 The boxes on the left represent sources of data and information regarding health interventions natural history of a disease to assess the chances of disease incidence and progression, and testing or treatment benefit and harm coupled with health outcomes, length of life, costs, and quality of life. For each strategy, the likelihood of the resulting outcomes (probabilities) are then coupled with the value of the outcomes to determine the costs and effectiveness, which leads to a decision and action that forms health policy and patient care choices. The boxes at the top represent potential perspectives for the analysis and the four main types of economic analysis that can also inform the decision and action.

TABLE 3.2
World Health Organization cost-effectiveness thresholds based on per capita gross domestic product

Region	Subregions—patterns of child and adult mortality*	Example country within region	2005 cost-effectiveness threshold (US\$)
Afro (Africa)	D, E	South Africa	6,000
Amro (Americas)	A, B, D	United States (A)	120,000
Emro (Eastern Mediterranean)	B, D	Saudi Arabia	31,000
Euro (Europe)	A, B, C	United Kingdom (A)	90,000
Searo (Southeast Asia)	B, D	Thailand	15,000
Wpro (Western Pacific)	A, B	China	21,000

The threshold for high cost effectiveness equals the cost-effectiveness threshold divided by 3 (e.g., \$40,000 for the United States and \$30,000 for the United Kingdom).
*Each region is divided into subregions based on patterns of child and adult mortality in groups ranging from A (lowest) to E (highest).
Data from World Health Organization. Table: threshold values for intervention cost-effectiveness by region. 2005. Available at www.who.int/choice/casts/CER_levels/en/index.html. Accessed February 10, 2013.

patients in the cohort die or until a fixed time has elapsed. By tracking survival, quality of life, and costs for each cohort member, the Markov model estimates life expectancy, quality-adjusted life expectancy, and life-time costs. By accounting for the time elapsed, these disease models can discount both costs and quality-adjusted life expectancy. In such models, innovative treatments may provide value by prolonging life (e.g., decreasing the risk of dying after becoming sick), by decreasing the likelihood of becoming sick (e.g., preventing morbidity, improving quality of life), and by lowering disease costs through avoidance or delay of expensive disease complications (e.g., surgery).

Cost effectiveness

How much one is willing to pay for something depends in part on one's financial situation. Similarly, for health care policymakers, what is considered to provide value or to be "cost effective" may depend on each country's economy and its willingness to pay for that benefit. Consequently, the World Health Organization (WHO) bases cost effectiveness on the country's economic status as measured by that country's gross domestic product.²⁴ According to WHO, an intervention is considered to be cost effective if the incremental cost-utility ratio falls below three times that country's per capita gross domestic product. An intervention is highly cost effective if the ratio falls below that country's per capita gross domestic product. WHO has established cost-effectiveness thresholds for six regions based on their per capita gross domestic product (Table 3.2).²⁵

For comparison, although some recommend \$100,000 or even \$300,000 thresholds in the United States,²⁶ the frequently cited cost-effectiveness threshold is \$50,000 per QALY gained, which is similar to the WHO threshold for "high cost effectiveness." In the United Kingdom, NICE methods guidance suggests a threshold of £20,000 to £30,000²⁷ (about €25,000 to €35,000, or \$40,000 to \$56,000) per QALY, similar to the "highly cost-effective" WHO UK threshold, but as in the United States, some recommend raising it to £70,000 (\$110,000).²⁸

Raising the willingness-to-pay threshold not only expands the number of treatments that become "cost effective," but also has implications for the benefit per expenditure. For instance, spending \$100,000 on strategies with an ICER of \$100,000 per QALY gained would buy 1 year, whereas spending it on those with an ICER of \$50,000 per QALY gained would yield 2 years. In particular, policymakers should consider whether these last few dollars spent "at the margin" on health care treatments with higher ICERs would yield greater societal benefit if spent elsewhere.

Budgets

In addition, allocating resources strictly on a cost-effectiveness basis does not account for yearly budgets because these cost-effectiveness analyses consider a lifetime time horizon, including future cost savings from disease prevention or reduction in morbidity or mortality. For maximally efficient resource allocation, policymakers would establish their health care budget for the fiscal year, and then treatments would be funded going in order from cost-saving ones to those with the lowest incremental cost-effectiveness ratios up to those with the highest while accounting for their budget impact (based on next year intervention costs, disease prevalence, treatment eligibility, and available health delivery infrastructure) until the budget is entirely expended. In this case, the societal willingness-to-pay threshold would be

TABLE 3.3
Analysis on treatment sequences of disease-modifying antirheumatic drugs

Strategy	Example
Monotherapy	DMARD monotherapy (e.g., methotrexate followed by sulfasalazine)
Steroid	Glucocorticoids with DMARD monotherapy (e.g., methotrexate)
Parallel	Two or more DMARDs (e.g., TICORA2 triple therapy arm)
Step up	One or more DMARDs added to prior monotherapy (e.g., BeSt step-up arm or TICORA routine arm)
Step down	Parallel DMARDs with subsequent removal of DMARDs (e.g., COBRA, Fin-RACo trials)
Intensive	DMARD doses rapidly increased to reduce the Disease Activity Score and keep it at low levels of activity (e.g., TICORA and TICORA2 intensive arms)

COBRA, Combinatie therapie Bij Reumataide Artritis (Dutch for combination therapy for rheumatoid arthritis); DMARDs, disease-modifying antirheumatic drugs; Fin-RACo, Finnish Rheumatoid Arthritis Combination Therapy (trial); TICORA, Tight Control for Rheumatoid Arthritis (study).

the funded intervention that had the highest ICER. However, policymakers may also consider other attributes such as equity or fairness, the distribution of benefits to some and not others.¹¹

ECONOMIC APPLICATIONS IN RHEUMATIC DISEASES

Rheumatoid arthritis

As examples of applications of these economic principles, NICE has used the approach outlined earlier in health technology assessment to examine rituximab (which was recommended),²⁹ certolizumab pegol (which was not recommended),³⁰ and abatacept (which was not recommended for refractory RA).³¹ For active RA, NICE recommends adalimumab, etanercept, or infliximab but only if the Disease Activity Score (DAS28) exceeds 5.1 on at least two occasions that are at least a month apart and if patients have tried two disease-modifying antirheumatic drugs (DMARDs) including methotrexate.³²

To explore economic evaluation in more detail, the National Collaborating Centre for Chronic Conditions (NCCCC), which is an independent body funded by NICE, has developed a national clinical guideline for RA.³³ The guideline process takes into account economic considerations as recommended by the Grading of Recommendations Assessment, Development and Evaluation (or GRADE) Working Group. The clinical guideline group sought to examine the introduction and optimal sequencing of DMARDs in their translation of evidence into recommendations. Seeking to focus less on particular drugs and more on treatment sequences, their analysis considered six strategies (Table 3.3).

TABLE 3.4

Incremental cost effectiveness of six alternative rheumatoid arthritis treatment strategies from lowest to highest lifetime costs

Strategy	Lifetime cost (US\$)	Quality-adjusted life expectancy (years)	Incremental cost (US\$)	Incremental quality-adjusted life expectancy (years)	Incremental cost-effectiveness (\$ per quality-adjusted life-year gained)
Step down	78,158	15.32			
Step up	81,266	11.91	3,107	−3.41	Dominated*
Parallel	88,917	13.42	10,758	−1.90	Dominated*
Monotherapy	89,594	13.73	11,435	−1.59	Dominated*
Steroid	91,949	11.79	13,790	−3.53	Dominated*
Intensive	97,674	15.77	19,515	0.45	27,104

*Dominated by step down because it costs more yet yields lower quality-adjusted life expectancy than step down.

Trials with similar strategies were combined in a network meta-analysis of 13 randomized controlled trials to estimate the relative ACR20 and ACR50 efficacies of these alternative strategies. Treatment withdrawal rates were also based on these randomized controlled trials. Poorer Health Assessment Questionnaire (HAQ) scores were translated into lower quality of life (from 0.857 for quality of life for HAQ score of less than 0.25 to 0.034 for quality of life for HAQ score of more than 2.75 to 3) and into higher resource use (in terms of frequency of hospitalizations and office visits and the likelihood of joint replacements). Drug costs were based on the literature and national unit costs.

The computer model simulated the prognosis and costs for an individual patient (based on age, sex, and HAQ score) selected from the UK RA survey. An exact hypothetical clone of that patient was treated using each of the six treatment strategies. Over the initial 6-month period, that patient may have had a response (ACR20 or ACR50) or no response. A random number generator applied to the likelihood of each of these responses determined which path the patient took. ACR20 or ACR50 responses led to improved HAQ scores initially, but with continued therapy, HAQ scores gradually worsened until therapy was withdrawn due to loss of efficacy or an adverse event. The patient's HAQ score then worsened by the same amount by which it initially improved, and the patient then started the next therapy in that patient's particular strategy. Patients who did not respond initially moved on to the next therapy in their sequence. After two DMARD failures, a patient received biologic therapy. The simulation was continued for each patient until death. By tracking cost, quality of life, and length of life for each 6-month period for each patient over time, the computer simulation calculated quality-adjusted life expectancy and cumulative lifetime costs for each strategy for that patient. When the simulation for one patient was completed, a second hypothetical patient was then analyzed.

Table 3.4 displays the results for 100 patients run through 1000 simulations with cost converted into U.S. dollars (assuming \$1.60 = £1 here and below). To calculate the ICERs, strategies are rank-ordered from lowest to highest cost. The additional cost (incremental cost) and benefit (incremental effectiveness) compared with the next cheapest strategy is then calculated. When a strategy is more expensive but less effective (with lower quality-adjusted life expectancy), then the incremental effectiveness is negative and that strategy is “dominated” or inferior to the cheaper one and should not be considered. The next more expensive strategy is then compared with the cheaper nondominated strategy. In Table 3.4, all strategies are “dominated” by the step-down strategy except for the intensive strategy, which has an ICER of \$27,104 per QALY gained compared with the step-down strategy, falling within the WHO range considered highly cost-effective in the UK and also within the range that is likely acceptable for NICE.

Osteoarthritis

The UK NCCCC has also developed a national clinical guideline for osteoarthritis.³⁴ The guideline compared the cost effectiveness of nonsteroidal antiinflammatory drugs (NSAIDs) and cyclooxygenase-2 inhibitors with placebo or acetaminophen for 3 months in 55-year-olds with osteoarthritis symptoms by considering the drugs' cost, gastrointestinal adverse events (dyspepsia, gastrointestinal bleeding, ulcer), cardiovascular adverse events (myocardial infarction, stroke, heart failure), and effectiveness as measured by a meta-analysis examining Western Ontario and McMaster Universities (WOMAC) Osteoarthritis Index scores, which were then translated into quality-of-life values. To mitigate gastrointestinal risk, NSAIDs in combination with proton pump inhibitor (PPI) strategies were also considered. Fig.

Fig. 3.4 Each diamond represents the unique combination of lifetime costs and quality-adjusted life expectancy (QALE) for each nonsteroidal antiinflammatory drug therapy with or without a proton pump inhibitor (PPI). The line represents all of the nondominated strategies at the cost-effectiveness frontier. All strategies that fall below the line (not identified for clarity) are either dominated (cost more and have lower QALE) or are weakly dominated (less efficient use of resources); for example, naproxen + PPI. Notice that moving toward the right, the cost-effectiveness frontier line flattens as the incremental cost-effectiveness ratio rises, which demonstrates that these strategies are a less efficient use of resources than those on the left side of the frontier.

3.4 displays the results as a *cost-effectiveness frontier*. All strategies falling below the frontier are inferior, either dominated (more expensive and less effective) or a less efficient use of resources, termed *extended* or *weak dominance*.

As an illustration of extended or weak dominance (Table 3.5), spending \$1 million on naproxen + PPI extends population prognosis by 6.3 QALYs (\$1 million ÷ \$160,000), but spending \$1 million on ibuprofen + PPI extends population prognosis by 18.9 QALYs (\$1 million ÷ \$52,800). Because 18.9 QALYs with ibuprofen + PPI exceeds the 6.3 QALYs with naproxen + PPI, by extended dominance naproxen + PPI should not be considered because it would be a less efficient use of resources (it would yield fewer life-years). Consequently, ibuprofen + PPI is compared with diclofenac + PPI when its ICER is calculated.

The previous analyses consider economic costs, but the numerator could also be harm. For example, in the same analysis, the guideline provides the likelihood of gastrointestinal events per 10,000 person-years. When gastrointestinal events are substituted for costs, celecoxib + PPI becomes the dominant strategy because it yields the lowest risk of gastrointestinal events (even lower than placebo or acetaminophen) and yields the highest quality-adjusted life expectancy. On the other hand, when cardiovascular events are considered, celecoxib + PPI, compared with ibuprofen + PPI, results in an additional 25,800 cardiovascular events for every QALY gained by the population. These cardiovascular and gastrointestinal analyses, however, focus

TABLE 3.5
Incremental cost-effectiveness with extended dominance (excluding a weakly dominated strategy that is a less efficient use of resources)

Strategy	Lifetime cost (US\$)	Quality-adjusted life expectancy (years)	Incremental cost (US\$)	Incremental quality-adjusted life expectancy (years)	Incremental cost effectiveness (\$ per quality-adjusted life-year gained)*
Didofenac + PPI	2003.20	10.9635			
Naproxen + PPI	2019.20	10.9638	48.00	0.0003	160,000
Ibuprofen + PPI	2024.00	10.9648	4.80	0.0010	52,800
Didofenac + PPI	2003.20	10.9635	32.00		
Naproxen + PPI	2019.20	10.9638	48.00	0.0003	Weakly dominated
Ibuprofen + PPI*	2024.00	10.9648	52.80	0.0013	16,000

**Because naproxen + PPI is weakly dominated, ibuprofen + PPI is compared with didofenac + PPI. PPI, proton pump inhibitor.*

only on harm. For comparison, the previous quality-adjusted life expectancy analysis combines the cost of these complications and their quality of life impact as well as their effect on osteoarthritis.

Osteoporosis

Finally, the NCCCC has also developed a national clinical guideline for osteoporosis: assessing the risk of fragility fracture.³⁵ The use of risk assessment tools to determine susceptibility to fracture requires physician time but may be beneficial by facilitating prevention of fragility fractures. However, if the risk assessment tool overestimates fracture risk, then treatment and its cost may be unnecessary. Alternatively, if the risk assessment tool underestimates fracture risk, beneficial preventive treatment would be omitted, which could lead to preventable hospitalization costs and morbidity.

In a cost analysis, the guideline compared the cost of bone mineral density scanning for all patients with the cost of determining a risk score followed by bone mineral density scanning only if the score is positive. The analysis considered both the FRAX and QFracture tools, with negligible cost difference between the two. For comparison, physician time to perform the risk assessment was \$58 versus \$123 for the bone density scanning. Additional consultation time for conveying results and discussion of treatment was also considered. The cost minimization analysis determined when the cost of using the risk score for screening would equal the cost of bone

density scanning for all patients. For example, in simplistic terms, if all patients have a positive screening result when risk is scored, then risk screening adds unnecessary cost (physician time) that can be avoided by directly referring all patients for bone density scanning. Conversely, if no risk-screened patients are referred for bone density scanning, then bone density screening for all will be a needless cost. The analysis found that if fewer than 68% of patients undergoing the FRAX and QFracture risk stratification process were referred for bone density scanning based on positive screening results, then risk stratification would be less costly than performing bone mineral density testing for all.

CONCLUSION

Economic analyses in medicine include cost minimization, cost-benefit, cost-effectiveness, and cost-utility analyses. The most commonly applied method in health care is cost-utility analysis, which is often used for health technology assessment to determine the most efficient use of resources. Beyond cost-effective use of resources, however, equity issues and budget impact analyses affect policymaker decisions. For physicians, these economic analyses can help inform cost-effective care, such as in determining treatment strategies in RA and osteoarthritis, and assessing the risk of fragility fractures in osteoporosis.

The synovium

■ MALCOLM D. SMITH ■ MIHIR D. WECHALEKAR

- Synovium lines diarthrodial joints, tendon sheaths, and bursae.
- Specialized functions of synovium include nonadherence, control of synovial fluid volume and composition, and chondrocyte nutrition.
- The normal synovium expresses low levels of proinflammatory cytokines and some anti-inflammatory cytokines. In addition, the low levels of expression of RANKL (receptor activator of nuclear factor κ B ligand) with high levels of expression of OPG (osteoprotegerin) result in a low RANKL-OPG ratio that suppresses osteoclast formation. This balance is likely to be important in maintaining homeostasis in the normal, noninflamed synovium.
- Cadherin-11 expression by synovial fibroblasts may be critical for the development of the synovial lining by facilitating cellular organization, compaction, and matrix development.

DEFINITIONS

Synovium is the soft tissue lining the spaces of diarthrodial joints, tendon sheaths, and bursae. The term includes both the continuous surface layer of cells (intima) and the underlying tissue (subintima). The intima is composed of specialized macrophages and fibroblasts, and the subintima contains blood and lymphatic vessels, a cellular content of both resident fibroblasts and infiltrating cells in a collagenous extracellular matrix. Between the intimal surfaces is a small amount of fluid, usually rich in hyaluronan (hyaluronic acid). Together, this structure provides a nonadherent surface between tissue elements. Unlike serosal surfaces, which also have nonadherent properties, synovium is derived from ectoderm and does not contain a basal lamina.

The study of synovial tissue is of major importance in understanding the pathogenesis of inflammatory arthritis, including rheumatoid arthritis (RA) and seronegative spondyloarthritis (SpA). Despite this, our knowledge of the immunohistochemical architecture of the synovial membrane, particularly in normal subjects, is surprisingly limited.

In normal subjects, the synovium comprises an intimal layer, which is 20 to 40 μ m thick in cross section, and an areolar subintima, which can be up to 5 mm in thickness. At many sites there is no discrete membrane, especially where subintima consists of fat pad or fibrous tissue.

Synovium is often atypical. Intimal cells may be absent. Superficial bursae contain little or no hyaluronan-rich fluid.¹ Ganglia are sacs containing hyaluronan-rich fluid but do not occur at sites of shearing and do not have a typical intima and so may not be considered really to be synovial tissue. Diseased synovial tissue may lose any recognizable lining structure and only be definable by its relation to a joint. These variations probably reflect interplay of several factors in synovial histogenesis.

EMBRYOLOGY

In the early embryonic limb bud, a central core or blastema that will form the skeleton appears. Within this core, foci of cartilage appear, each destined to become a bone. Blastemal cells around cartilage foci form a perichondrial envelope showing strong CD44 expression. The area where this envelope lies between cartilage elements is known as the *interzone*, from which synovium forms. The perichondrium forming a sleeve around each cartilage element subsequently invades the cartilage to form bone marrow. Thus

synovial and bone marrow stromal cells come from the same embryonic stock.

Shortly before the joint cavity forms, CD55 expression appears on cells along the joint line,² followed later by vascular cell adhesion molecule 1 (VCAM-1) expression. After cavity formation the intimal layer also takes on a higher level of expression of CD44 and β_1 integrins compared with subintima.

The mechanism of cavity formation is not fully understood; a working hypothesis implicates interactions between interzone cells bearing CD44 (a hyaluronan receptor) and hyaluronan itself.^{3,4} Shortly before cavity formation, the cells of the potential joint line show high uridine diphosphoglucose dehydrogenase (UDPGD) activity, which suggests increased hyaluronan synthesis. At the time of cavity formation high levels of hyaluronan appear along the joint line, saturate CD44, and induce disaggregation; at low concentrations hyaluronan cross-links CD44 molecules on adjacent cells, inducing cell aggregation.

Cavity formation might be expected to require lysis of matrix fibers. However, in human joints cavity formation is not associated with high local levels of matrix metalloproteinases (MMPs) at the joint line, and matrix fibers appear to run only parallel to the joint line before cavity formation; apoptotic cells found in the interzone at this time are not localized to the joint line and are unlikely to contribute to cavity formation. It appears, therefore, that development of the joint cavity arises more from differential tissue expansion than through loss of solid elements.

An alternative explanation for the formation of the synovial lining and the synovial-lined joint space has recently been suggested by mouse model work.⁵ A study (that awaits human replication) of cadherin-11-deficient mice suggests that expression of cadherin-11 on synovial fibroblasts may be critical in the development of a recognizable synovial lining by facilitation of cellular organization, compaction, and matrix development; this raises the possibility that cadherin-11 expression by synovial fibroblasts is critical for normal synovial tissue development.

STRUCTURE

The microscopic anatomy of synovial tissue was first fully described by Key,⁶ who divided synovium into three main types on the basis of subintimal structure: fibrous, areolar, and adipose (Fig. 4.1a to c). He also noted that subintima may be periosteum, perimysium, or even hyaline or fibrocartilage.

Areolar synovium is the most specialized form (see Fig. 4.1a). It is often crimped into folds, which may disappear when stretched. Less often it carries projections or villi. A more or less continuous layer of cells lies two or three deep on the tissue surface.^{7,8} Immediately beneath these cells are capillaries. Further into the tissue there is a plexus of small arterioles and venules,^{9,10} associated with mast cells. Lymphatic vessels can be found in all types of normal synovial tissue, although they are infrequent in the fibrous type of normal synovium.¹¹ In normal synovium, most lymphatic vessels are found in the deep subintima and fibrous layers, whereas in synovium from RA patients lymphatic vessels are widespread and numerous. Nerve fibers are present, chiefly in association with blood vessels.¹² Three layers of tissue matrix may be distinguished. The intima is associated with a fine fibrillar matrix with few type I collagen fibers.¹³ Beneath this is a layer relatively rich in type I collagen, which forms the physical membrane. Deeper is a loose layer that allows the membrane to move freely. Beyond the loose layer lies ligament, tendon, or periosteum.

Adipose synovium occurs as fat pads and within villi (see Fig. 4.1b). It has a complete intimal cell layer and a superficial net of capillaries. The intima may lie directly on adipocytes, but there is usually a band of

Fig. 4.1 (a) Areolar form of synovium (hematoxylin-eosin). (b) Adipose form of synovium (hematoxylin-eosin). (c) Fibrous form of synovium (hematoxylin-eosin). (Magnification $\times 200$)

collagen-rich substratum, whereas the deeper tissue is fat. Villi usually have a central arteriole and venule but can be avascular. The amount of fat in villi varies and probably decreases with age, with an increase in fibrous tissue.

Fibrous synovium is often difficult to define, consisting of fibrous tissue such as ligament or tendon on which lies an intermittent layer of cells (see Fig. 4.1c). Fibrous synovium may be indistinguishable from fibrocartilage, especially in the annular pads found in finger joints.

Intimal cells

Two types of intimal cells have been defined by electron microscopy, one consistent with a macrophage (type A) and the other with a fibroblast (type B).¹⁴ It is now generally accepted—from immunohistochemical and other lines of evidence—that intimal macrophages are true macrophages, derived from precursors in the bone marrow (although it is not certain if differentiation occurs *in situ* or before arrival), whereas the intimal fibroblasts are locally derived.¹³⁻¹⁶ In normal healthy synovium, synovial fibroblasts are the dominant cell population.¹⁷

Immunohistochemical and cytochemical methods have superseded electron microscopy as tools for cell identification.¹⁸ Intimal macrophages can be distinguished by their nonspecific esterase (NSE) activity and expression of surface markers such as CD68 and CD163. Intimal fibroblasts show intense activity of the enzyme UDPGD and prominent expression of VCAM-1 and CD55 (complement decay-accelerating factor [DAF]). In most disease states such as RA, intimal cells increase in size and number (Fig. 4.2). This is not *hyperplasia* but a complex change in cell populations, in terms of both origin and function, often dominated by macrophage influx.¹⁷

Synovial macrophages

Macrophages are present in both the intima and subintima. Intimal macrophages carry typical macrophage lineage markers. They show prominent NSE activity and are strongly positive for CD163 and CD68 but less so for CD14 (Fig. 4.3). Macrophages also express the immunoglobulin receptor Fc γ RIIIa. Strong Fc γ RIIIa expression is restricted to a subset of macrophages that correspond closely to sites of macrophage activation in rheumatoid disease: synovial, alveolar, serosal, scleral, salivary gland; lymphoid tissue and bone marrow; and Kupffer cells.¹⁹ Subintimal macrophages are Fc γ RIIIa dull or negative. Macrophages also express Z39Ig, a recently described inducible cell surface receptor linked to the classic complement pathway; Z39Ig expression can occur during macrophage differentiation and induce activation of the transcription factor nuclear factor κ B (NF- κ B) and production of matrix-degrading MMP-9.²⁰

Macrophages make up a minority of cells in normal intima (Figs. 4.3 and 4.4). In disease the proportion of macrophages may rise to 80% (see Fig. 4.2). Distribution varies, but a common pattern occurs: a superficial layer of macrophages with an intimal phenotype; beneath this a layer of intimal fibroblasts; and further beneath and beyond the limits of the intima, a zone of NSE-weak, strongly CD14+ and Fc γ RI+ macrophages, associated with venules. The deep, strongly CD14+ cells are probably freshly recruited cells and the superficial cells more mature.

In addition to true macrophages, there may be a small number of antigen-presenting interdigitating dendritic cells in normal synovial intima; these are more frequent in disease with greater overlap of markers, which confounds interpretation.^{21,22} Cells with features of osteoclasts such as expression of tartrate-resistant acid phosphatase and the vitronectin receptor also often appear in inflamed synovium. However, fully typical osteoclasts with

Fig. 4.2 Synovium in rheumatoid arthritis ($\times 400$) showing a thickened intimal layer containing mainly CD68+ macrophages (red) on the surface and weakly CD55+ fibroblastic cells beneath (blue).

Fig. 4.3 Synovial macrophages. Normal synovium ($\times 200$) stained for CD68+ macrophages (red).

calcitonin receptors may be restricted to pigmented villonodular synovitis and giant cell tumors of tendon sheath.

Synovial fibroblasts

The synovial intima contains cells adapted to hyaluronan production. In normal synovium CD68- intimal fibroblasts alone demonstrate high activity of the enzyme UDPGD.²³ UDPGD converts UDP-glucose into UDP-glucuronate, one of the two substrates required by hyaluronan synthase for hyaluronan polymer assembly. Unlike the activity of many other enzymes, UDPGD activity in intimal fibroblasts is reduced, rather than enhanced, in diseased tissue. Synovial intimal fibroblasts express CD55 (see Fig. 4.4), a feature distinguishing them from intimal macrophages.^{24,25}

Cells disaggregated from inflamed synovium and grown in tissue culture display fibroblast characteristics and ramifying processes with production of high levels of metalloproteinases.²⁶ It is not known whether they derive from intimal or subintimal cells. In tissue sections, immunoreactivity for

Fig. 4.4 Normal synovium (×200) stained for CD55+ fibroblasts, which are the predominant cell in the normal synovium intimal layer (contrast with Fig. 4.2).

Fig. 4.5 Normal synovium (×200) stained for vascular cell adhesion molecule 1.

collagenase and gelatinase is patchy and not necessarily confined to the intima.

Synovial intimal fibroblasts also show prominent expression of several adhesion molecules,^{8,27,28} including VCAM-1, intercellular adhesion molecule 1, CD44, and β_1 and β_3 integrins. Expression of VCAM-1 (Fig. 4.5) is particularly unusual, being absent from most other normal fibroblast populations, whereas CD44 and β_1 integrins are present at lower levels. The role of VCAM-1 with respect to intimal fibroblasts is puzzling, but it may modulate cell traffic; its ligand, $\alpha_4\beta_1$ integrin, is present on mononuclear leukocytes but not granulocytes. Intimal fibroblasts may allow transmigration of polymorphs but not mononuclear cells into synovial fluid, potentially trapping inflammatory cell infiltrates within the synovial membrane in disease states such as RA.

Recently, the presence of both clusterin (a glycoprotein involved in recycling and apoptosis) and podoplanin (a membrane glycoprotein with diverse functions) has been reported in normal synovial fibroblasts; interestingly, podoplanin (which in the setting of neoplasia is associated with poor prognosis and metastatic disease) has been shown to be highly expressed in RA synovial fibroblasts with their attendant migratory and invasive potential.^{29,30}

The expression of two other surface molecules by synovial fibroblasts is noteworthy. Complement receptor 2 (CR2, CD21) is not expressed by normal intimal fibroblasts but has been induced on synovial fibroblasts in culture, in contrast to other fibroblast populations.³¹ DAF, VCAM-1, and CR2 are all involved in B-lymphocyte survival, as is a bone marrow stromal cell marker, BST-1, reported to be expressed on fibroblasts in rheumatoid, but not normal, intima.³² Other molecules associated with bone marrow stromal cells such as the chemokine stromal cell–derived factor-1 and bone morphogenetic proteins and their receptors,^{33–35} are expressed by synovial fibroblasts under various conditions. Moreover, lubricin, otherwise known as *superficial zone protein*, a glycoprotein found in synovium and the superficial zone of articular cartilage,³⁶ derives from the same gene as megakaryocyte-stimulating factor. A defect of this gene leads to CACP (camptodactyly arthropathy coxa vara pericarditis) syndrome. As indicated earlier, these patterns of gene expression may reflect a common embryologic origin for synovial and bone marrow stromal cells.

Self-renewing mesenchymal stem cells that compare favorably with bone marrow–derived mesenchymal stem cells in terms of their ability to differentiate into bone, cartilage, and adipose tissue have been isolated from the normal synovium; it is unclear which component of the synovial membrane is home to these cells.^{37,38}

Intimal matrix

Intimal matrix has an amorphous or fine fibrillar ultrastructure. It is poor in type I collagen but contains minor collagens III, IV, V, and VI^{39,40} as well as laminin, fibronectin, and chondroitin-6-sulfate–rich proteoglycan, which, with collagen IV, are components of basement membrane; however, the basement membrane is conspicuous by its absence beneath the intimal layer. The looser structure of intimal matrix may be explained by the absence of entactin, which links other components in basement membrane together. Intimal microfibrils are of two types: fibrillin-1 microfibrils form a basket-work around cells, whereas collagen VI microfibrils form a uniform mesh.

Intimal matrix contains large amounts of hyaluronan (Fig. 4.6), which tails off 20 to 50 μm deep; this possibly indicates diffusion from the surface toward clearing lymphatics.

Fig. 4.6 Normal synovium stained for hyaluronan using a histochemical probe derived from proteoglycan core protein hyaluronan-binding region. Staining is most intense surrounding the lining cells and decreases further into the tissue. (Magnification ×200)

Fig. 4.7 Normal synovium (×200) stained with factor VIII to demonstrate the vascular network.

Vascular net

A rich microvascular net lies beneath the synovial surface.^{9,10} Capillaries (prominent in children and decreasing with age) occur just below or within the intima (Fig. 4.7). Some capillaries are fenestrated, and fenestrae tend to face the tissue surface⁴¹; 50 to 100 μm beneath the surface small venules are prominent. The endothelial cells lining the capillaries in normal synovium express cadherin-11 (Fig. 4.8). About 200 μm beneath the surface, larger venules, together with arterioles and lymphatics (Fig. 4.9),¹¹ form an anastomosing quadrilateral array. Vessels with lymphatic staining characteristics are prominent in RA synovium, a disease state in which increased turnover of hyaluronan and leukocyte trafficking is seen. It has been proposed that failure of lymphatic drainage of synovial fluid is a cause of villous proliferation in RA synovial tissue. If this is correct, it is likely to be due to overloading of existing lymphatic channels with hyaluronan-rich extracellular fluid and leukocytes rather than a lack of lymphatic channels.¹¹

Fig. 4.8 Normal synovium ($\times 400$) stained with an antibody against cadherin-11.

Fig. 4.9 Normal synovium ($\times 200$) stained with lymphatic vessel endothelial hyaluronan receptor-1 (LYV-1) antibody to demonstrate the lymphatic network.

Fig. 4.10 Normal synovium ($\times 200$) stained with an antibody to detect the interleukin-1 receptor antagonist.

Fig. 4.11 Normal synovium ($\times 200$) stained with an antibody against osteoprotegerin, a naturally occurring inhibitor of osteoclast formation.

Apart from the fenestration of superficial capillary endothelial cells, there is little evidence of specialization in synovial endothelium. Endothelial cells enlarge in inflamed tissue and microvascular proliferation can occur, but these events are common to inflammation at many sites. Tissue-specific adhesion molecules, or *addressins*, have been sought, but nothing conclusive has been found. However, there remains the possibility that specialized lymphocyte traffic pathways apply to synovium, possibly based on chemokine-receptor interactions.

CELL ORIGINS AND RECRUITMENT

Evidence to date indicates that both intimal and subintimal macrophages derive from bone marrow via circulating monocytes, many of which probably arrive through subintimal venules and migrate to the intima.

Intimal fibroblasts are thought to arise by division within synovium, but the site remains uncertain; they might be a discrete self-replicating population, distinct from subintimal fibroblasts, but several pieces of evidence argue against this. Rates of cell division within the intima are very low, even in disease. Following arthroplasty or synovectomy, intimal cells—likely replaced from the subintima rather than arising from intimal rests—reappear and express CD55, UDPGD, and VCAM-1. Disaggregated and cultured synovial fibroblasts lose VCAM-1 and CD55 expression, but the majority, apparently including cells of subintimal origin, will readily express these markers following cytokine stimulation, in contrast to fibroblasts of dermal or subcutaneous origin. These findings suggest that synovial fibroblasts, in both the intima and subintima, belong to a specialized population with a propensity to express VCAM-1 and CD55.

Two recent studies^{7,8} have demonstrated the range of cells that can be found in the synovial subintima. CD3+ T cells, including CD4+, CD8+, and memory T cells, can be found within the normal synovial tissue; although they are likely to be simply trafficking through the normal synovium, their role, if any, in the homeostasis of synovial tissue is unknown. It is also possible to detect B cells, plasma cells, and granzyme B+ cells in normal synovium, although they are present in small numbers.

Although production of inflammatory cytokines, including interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α),⁸ can be detected in normal synovial tissue, it is far less than that seen in inflamed synovial tissue such as that in RA patients, and the amount of antiinflammatory cytokine production, at least in the case of IL-1 receptor antagonist (the naturally

occurring inhibitor of IL-1), is far greater than the amount of inflammatory cytokine seen (Fig. 4.10). This would achieve the desired result of suppressing an inflammatory process in the normal synovial tissue. Similarly, the amount of RANKL (receptor activator of NF- κ B ligand, an essential factor for the development of osteoclasts) seen in normal synovial tissue is low⁸ and far less than that of osteoprotegerin, its naturally occurring inhibitor (Fig. 4.11). The net result of this is to suppress the formation of osteoclasts within the normal synovium and preserve homeostasis within the normal joint.

FUNCTION

The functions of synovial tissue are often taken as evident but are remarkably difficult to define.⁴² Like other soft connective tissue, synovium provides a deformable packing that allows movement of adjacent, relatively nondeformable tissues. The difference between synovium and other soft connective tissue is that it allows most of the movement to occur between rather than within tissues. Areolar synovium may also have specialized viscoelastic properties for coping with the stretching, rolling, and folding it undergoes during joint movement.

Functions of the tissue relating to the cavity may be considered to be the following:

- Maintenance of an intact nonadherent tissue surface
- Lubrication of cartilage
- Control of synovial fluid volume and composition
- Nutrition of chondrocytes within joints

Maintenance of the tissue surface

Synovial surfaces must be nonadherent to allow continued movement. Animal models suggest that production of hyaluronan by intimal fibroblasts may be important in inhibiting adhesion.⁴³ Plasminogen activator and DAF from intimal fibroblasts may also inhibit fibrin formation and scarring. To retain synovial fluid, the intimal matrix must consist of a fibrous mat of a particular porosity that allows free exchange of crystalloids and proteins but inhibits rapid transit of the viscous hyaluronan solution that is an important component of the fluid. These functions presumably reflect the combined activities of the intimal macrophages and fibroblasts. The vasculature is

likely to be important in both intimal cell nutrition and recruitment of new cells. New macrophages are derived from blood monocytes that enter the tissue through venules, and perivascular fibroblasts may provide the main pool of intimal fibroblast precursors.

Lubrication

The ability of synovial fluid to lubricate cartilage surfaces depends on the presence of glycoprotein, especially a glycoprotein known as both *lubricin* and *superficial zone protein* because of its localization to the surface of synovium and cartilage.³⁶ Hyaluronan does not appear to contribute to the ability of synovial fluid to lubricate cartilage in *ex vivo* systems, but the glairy quality imparted by hyaluronan may be important in maintaining a film of lubricant on the cartilage surfaces *in vivo*.

Whatever the precise forces acting on fluid volume, the presence of hyaluronan is likely to be the main factor responsible for retaining a constant volume of fluid during exercise⁴⁴; this fluid is probably important as a cushion for synovial tissue and as a reservoir of lubricant for cartilage. It is likely that mechanical stimulation of intimal fibroblasts influenced by effectiveness of the synovial fluid cushion dictates the rate of synthesis and exportation of hyaluronan into the synovial fluid compartment. Thus when synovial fluid volume is high, reduced mechanical stresses on intimal fibroblasts result in reduced rate of hyaluronan production and vice versa.

Two distinct mechanisms create joint effusions. When synovium is mechanically irritated by worn bone and cartilage, the composition of the fluid remains reasonably normal. Excessive production of hyaluronan by intimal fibroblasts stimulated by frictional forces retains plasma dialysate in the synovial cavity; in synovitis the effusion is an accumulation of exudate similar to a pleural effusion (i.e., an overspill from the inflammatory edema in synovial tissue created by increased vascular permeability). Recent theories about a possible low-grade inflammatory and immune reaction contributing to the pathogenesis of osteoarthritis suggest that these two mechanisms of effusion development may not be as distinct as originally thought.⁴⁵ Additionally, recent proteomic evidence suggests that the increased vascular permeability of inflammation may be related not only to an increase in interendothelial gaps but also to glycocalyx damage and aquaporin upregulation.⁴⁶

Chondrocyte health and nutrition

The synovium provides the major route of chondrocyte nutrition. In normal joints a surprisingly large proportion of hyaline cartilage lies within 50 μm of a synovial surface. In any one position only a small proportion of cartilage is apposed to the other articular surface, and synovium packs most of the space between less congruent areas. In immature joints the incomplete subchondral plate may contribute to nutrition, but in adult joints this route is unlikely to be significant. Nutrition of areas of cartilage that do not come into close contact with synovium (concave articular surfaces in particular) must take an indirect route. Although a small proportion of nutrition may occur by smearing of a thin film of fluid over these surfaces during movement, indirect routes through cartilage matrix and the apposed articular cartilage may be more important.⁴

Diarthrodial joints (in both cartilage and synovium) have been found to have high levels of transforming growth factor- β (TGF- β), a latent complex that requires activation to induce a biological response. Recent *in vivo* experiments suggest that shearing of synovial fluid because of physiologic joint motion may play an important role in TGF- β activation, which may be essential to maintain the biochemical content and structural integrity of healthy cartilage.^{47,48}

Despite the fact that the vessels in synovium provide the most direct route for cartilage nutrition, there is no evidence that they are structurally

adapted to this function. The fenestrae seen in superficial capillaries are present in tendon sheath synovium at sites where there is no cartilage (or tendon) dependent on their supply of small molecules.

SYNOVIUM AS A TARGET FOR IMMUNOLOGIC DISEASE

Synovial joints are involved in several immunologic or inflammatory disorders, including RA, systemic lupus erythematosus, and seronegative spondyloarthritis. Except in relapsing polychondritis, patterns of inflammatory rheumatic disease indicate targeting of synovium or enthesis rather than cartilage. Perhaps the most important reason for studying the biology of synovium is to obtain insight into which immunopathologic processes are likely to be suitable therapeutic targets in inflammatory arthritides.

Autoimmune responses to synovial antigens might theoretically occur, but evidence is lacking. Moreover, none of the clinical syndromes indicates targeting of joints alone. Associated targeting of other tissues such as pericardium or uveal tract requires an explanation. Few, if any, synovium-specific antigens are known, and when rheumatic disorders are associated with autoantibodies, the antigens involved are ubiquitous. In seronegative spondyloarthritis it is doubtful whether there is a true autoimmune response.

Understanding the microarchitecture of the normal synovium, including the wide range in microscopic appearances, cellular infiltrates, and production of cytokines, enzymes, and other biologically relevant proteins, assists in understanding the relevant changes in synovial tissue architecture and immunopathology in disease states. Although the architecture of the normal synovium is not as homogeneous as previously portrayed, consistencies across the broad spectrum of normal synovial tissues can be contrasted with those seen in chronically inflamed synovial tissue. The marked increase in synovial lining layer thickness with a reversal of the normal ratio of type A to type B intimal cells, which favors type B cells in normal synovium and type A cells in RA, is an example of this. Numerous other examples can be given, including the changes in subintimal cell content and cytokine, and chemokine production; vascular and lymphatic changes; and production of metalloproteinases and stimulators of osteoclast formation. A recent study in a mouse model of arthritis has also raised the possibility of cadherin-11 expression on synovial fibroblasts as a potential therapeutic target in the treatment of RA⁴⁹; inhibition of cadherin-11 interactions in this model interfered with both synovial inflammation and cartilage invasion by pannus, without having any effect on bone erosion (predominantly osteoclast dependent). In this model inflammation could be reduced substantially by antibodies to cadherin-11 or a cadherin-Fc fusion protein. Furthermore, cadherin-11 expression (see Fig. 4.8) has been found to promote invasive behavior of fibroblasts and is increased by IL-17 and TNF- α , cytokines very relevant in RA pathophysiology.⁵⁰⁻⁵²

Only two groups of enzymes found in the joint, cysteine cathepsins and MMPs, are capable of degrading native type I and II collagen fibrils. There is some evidence that cathepsin K may play an important role in the pathogenesis of osteoarthritis and RA and may be a potential therapeutic target in treating these conditions.³³ It is important to understand the hierarchy and chronology of these synovial changes in chronic inflammatory arthritides and contrast them with those seen in the normal synovium to identify suitable therapeutic targets at various stages in the evolution of a chronic inflammatory arthritis. The identification of TNF- α , IL-1 β , and IL-6 as two likely therapeutic targets is an example of how such a strategy can lead to the introduction of useful therapeutic interventions into the management of several chronic inflammatory arthritides, including RA, psoriatic arthritis, and ankylosing spondylitis.

There is still much to be learned about the immunologic microenvironment of articular tissues, particularly the normal synovium.

Articular cartilage

■ DICK HEINEGÅRD ■ PILAR LORENZO ■ PATRIK ÖNNERFJORD ■ TORE SAXNE

- The cells in cartilage maintain function of the extracellular matrix (ECM) via controlled turnover in response to minor damage caused by fatigue and altered load by removing malfunctioning matrix constituents by breakdown and producing new ones to achieve repair.
- The cell obtains feedback on the quality of the ECM via a number of cell-surface receptors such as integrins, DDR-2 (discoidin domain receptor 2), hyaluronan receptors, and proteoglycans with specificity for different matrix molecules.
- The composition of cartilage ECM is different close to cells in the territorial matrix than in the more distant interterritorial matrix. Composition also varies between different types of cartilage and from surface to deep articular cartilage.
- The ECM of cartilage contains a specific proteoglycan—aggrecan—that provides a very high fixed charge density and therefore an osmotic environment, with water retention being essential for tissue resilience. Aggrecan is also part of a network in which globular domains interact with other molecules.
- Fibrillar networks with collagen as the major constituent provide the tensile properties essential for load distribution and dissipation. The fibers contain other matrix proteins (e.g., those bound at their surface) that mediate interactions with other tissue structures, including neighboring fibers, which enhances their mechanical qualities.
- Cartilage ECM contains growth factors and proenzymes that are sequestered by binding to matrix macromolecules, and these substances can be released upon degradation of the carrier molecules.
- As a result of degradation of cartilage matrix, the fragments formed are released into surrounding fluids and can be used as indicators of the ongoing process, the so-called molecular marker technology.
- Fragments of ECM components can activate innate immune responses such as complement.

Articular cartilage has key roles in the function of joints. A major function is to take up and distribute load such that a given point of the underlying bone can handle very high strain. Another role of cartilage is to provide low-friction movement. One key feature of joint diseases is deterioration of joint function, which results from progressive damage to articular cartilage by degradation of the structural components important for properties of the tissue. Progressive joint destruction may eventually lead to total loss of the cartilage accompanied by alterations in underlying bone in the common disease of osteoarthritis (Fig. 5.1). Mechanisms triggering this tissue destruction are not known in detail, but it is clear that excessive load may induce a remodeling process that fails to restore normal cartilage. Stimulation of chondrocytes by cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α) induces the cells to degrade their surrounding matrix and can, over an extended period, result in total dissolution of cartilage *in vitro*. The identity of the individual enzyme or enzymes responsible for specific fragmentation of a particular matrix protein is not known, although in some cases candidates have been established. A repair response often accompanies the ongoing tissue destruction. In more serious cases this response is not sufficient, and tissue failure ensues.

A prerequisite for understanding the mechanisms of tissue destruction and failed repair is to know the functions of molecules in the extracellular

matrix (ECM) and how they are assembled into larger networks. It is equally important to understand the mechanisms involved in their degradation. One important and basic clinical observation in joint diseases such as rheumatoid arthritis and osteoarthritis is that after joint replacement, the inflammation recedes and the symptoms that have been plaguing patients are ameliorated or disappear in the vast majority of cases. This brings up the question of whether the components released from cartilage actually stimulate the inflammatory reaction.

The main structural entities in cartilage include aggrecan and collagen. The proteoglycan aggrecan has a primary role in taking up load and resisting deformation. The collagen network provides tensile properties, and the type VI collagen network may have a role in protecting the cell and guiding matrix assembly. A set of molecules close to the cells have specific functions in binding to particular cell-surface receptors and thereby provide signaling of conditions in the matrix.

This chapter therefore focuses on describing the individual cartilage macromolecules and, when possible, their functional properties and how they have implications for tissue assembly. In some instances, candidate enzymes have been implicated in having roles in the degradation of specific macromolecules and will be discussed.

OVERALL TISSUE ORGANIZATION

The part of the matrix closer to cells, the territorial matrix, has a somewhat different composition and structure than the matrix at some distance, the interterritorial matrix (Fig. 5.2) (for references, see Heinegård and colleagues¹). Examples of components found in both compartments are collagen type II fibers and aggrecan; in contrast, collagen type VI is found particularly in the territorial matrix, and cartilage oligomeric matrix protein (COMP) and cartilage intermediate layer protein (CILP) are primarily found in the interterritorial matrix of normal cartilage. There is also a difference in the composition of cartilage from the superficial to deep layers. In the superficial layer, collagen fibers are thinner and arranged in parallel with the surface of the tissue, whereas in the deeper layer the fibers are thicker and arranged perpendicular to the surface, with a transition zone in between them (Fig. e5.1; also see Fig. 5.1). The superficial part of cartilage is enriched with a number of noncollagenous molecules, notably lubricin and asporin. At the same time, other molecules are much less abundant in this part of the tissue, as exemplified by aggrecan, which is particularly enriched toward the deeper parts of the tissue (Heinegård and Önnérfjord, unpublished observation). Certain molecules such as CILP are found primarily in the middle portions of articular cartilage. Although a number of cartilage components have been described in recent years, our understanding of what specific requirements and functions are met by molecules with such a restricted localization in tissue is still very limited.

Different types of cartilage have markedly different compositions. Articular cartilage has major similarities, yet multivariate analyses of proteomics data have demonstrated differences between knee and hip articular cartilage.²

AGGREGAN

The major structure of aggrecan, illustrated in Figure 5.3,¹ consists of approximately 100 chondroitin sulfate glycosaminoglycan chains, each built from a disaccharide unit that is repeated some 50 times, but with extensive variability. Each disaccharide contains uronic acid with a negatively charged carboxyl group and an *N*-acetylgalactosamine with a sulfate in either the 4

Fig. e5.1 The organization of collagen fibers at different distances from the surface of articular cartilage is shown, as well as differences in fibril diameters between the pericellular, territorial, and interterritorial compartments.

Fig. 5.1 As an example, one cartilage protein (cartilage intermediate layer protein [CILP]) shows a distinct change in localization from distribution in normal cartilage in intermediate parts of the tissue and rather selectively in the interterritorial matrix to a prominence at the superficial parts and primarily in the pericellular compartment in the diseased cartilage. The different distribution of matrix proteins with depth of the articular cartilage is illustrated by way of three examples in the left diagram. OA, osteoarthritis.

or the 6 position. Each chain will therefore contribute around 100 negatively charged groups. The glycosaminoglycans are linked to a serine residue of the protein core of the proteoglycan via their reducing terminal end. The chains are clustered, and clustering differs between the two regions referred to as CS domain 1 and CS domain 2 (see Fig. 5.3). There is an additional glycosaminoglycan, keratan sulfate, that has a disaccharide building block of galactose and an *N*-acetylglucosamine with a sulfate in the 6 position. These chains are shorter and particularly enriched closer to the N-terminal end of the protein core, in the so-called keratan sulfate-rich region. The aggrecan molecule is composed of some 30 such chains.

The proteoglycan core protein contains globular domains flanking the three domains carrying glycosaminoglycan chains. The one most N-terminal, the hyaluronan-binding domain (G1 globe), contributes specific high-affinity binding of the aggrecan molecule to hyaluronan (see below). After a short interglobular domain there is a second globular domain (G2) that has structural similarities to the G1 globe but does not bind hyaluronan and has no known function. In the very C-terminal end of the aggrecan molecule there is a G3 globe with a lectin homology domain; it contributes by binding to other proteins (e.g., fibulins and tenascins), which themselves can form molecular complexes involving several such molecules (see Fig. 5.2). Recently, mutations that abolish binding of the G3 domain to the fibulins and tenascins have been shown to lead to familial osteochondritis dissecans.³

Many aggrecan molecules will bind to a single, very long strand of hyaluronan, thereby forming large aggregates containing more than 100 glycosaminoglycan chains, each with some 100 negatively charged groups. These charges are thus fixed in the tissue, and the presence of counter ions results in an osmotic environment that retains water and has an essential role in cartilage function by resisting compression and distributing load. The interaction of aggrecan via its G1 globe with hyaluronan is stabilized by the link protein having structures similar to the hyaluronan-binding domain of aggrecan. This link protein will bind to this domain of the proteoglycan, as well as to hyaluronan.

In normal cartilage turnover, as well as in pathology, the aggrecan molecule is cleaved by enzymes called aggrecanases (i.e., ADAMTS-4 [a disintegrin and metalloproteinase with thrombospondin-4 motifs] and ADAMTS-5)^{4,5} (see Fig. 5.3). One site of this cleavage is in the interglobular domain between the hyaluronan-binding G1 globe and the G2 globe. The cleavage occurs between the amino acids EGE and ARG (for references, see elsewhere⁶). The new N- and C-terminals formed have been used to develop antibodies that recognize the fragments produced only by the cleavage. These antibodies have in turn been used to demonstrate such fragments in body fluids and tissue extracts.^{6,7} The cleavage occurring in the domain carrying the chondroitin sulfate chains results in shortening of the aggrecan with ensuing decreased number of fixed charged groups (see Fig. 5.3). With aging, shorter aggrecan molecules accumulate, the extreme being hyaluronan-binding domain with no glycosaminoglycan-binding structures remaining.⁸ Indeed, in adults a major proportion of the aggrecan molecules found in the interterritorial matrix at a distance from the cells do not contain the G3, C-terminal globular lectin homology domain (Aspberg and Heinegård, unpublished observation). On the other hand, the molecules in the territorial matrix close to the cells contain this domain, probably a result of the gradual turnover of the aggrecan molecules. At the same time there is substantial accumulation of G1 domain, apparently retained by being bound to hyaluronan.⁹ This fragment can be identified in tissue either via its new C-terminal as represented by an -EGE³⁷³-COOH sequence formed through cleavage by aggrecanase or via a further matrix metalloproteinase (MMP) cleavage that forms a C-terminal -PEN³⁴¹-COOH sequence.¹⁰

Even from early experiments by Thomas¹¹ and Fitton-Jackson and collaborators¹² it was clear that chondrocytes have a remarkable capacity to replace aggrecan molecules removed from tissue by the use of enzymes cleaving hyaluronan. It appears that a normal chondrocyte should be able to replace even large amounts of proteoglycans lost unless suppressed by cytokines such as IL-1 and TNF- α .

There is increasing evidence that the aggrecan degradation encountered in early joint disease, such as osteoarthritis, is effectively counterbalanced

Fig. 5.2 Indicated are the interactions between extracellular matrix proteins and specific receptors at the cell surface. Note the different molecular composition of the territorial matrix closer to the cell than in the interterritorial matrix at some distance. CD44, receptor for hyaluronan; CHAD, chondroadherin; CILP, cartilage intermediate layer protein; COMP, cartilage oligomeric matrix protein; CS, chondroitin sulfate; HA, hyaluronan; HS-PG, heparan sulfate proteoglycan; KS, keratan sulfate; NC4, N-terminal globular domain of collagen 9.

by increased synthesis and deposition of the molecule such that no overall loss takes place.^{13,14}

COLLAGEN FIBRILLAR NETWORKS

A major function of the ropelike collagen fiber networks in cartilage is to provide tensile strength and distribute the load so that excessive local force is not applied to the underlying bone. One type of fiber contains a core of collagen type II with a minor constituent of collagen type XI connected via a number of molecules bound at its surface.

The other fibrillar network contains a core of collagen type VI that forms a filamentous network primarily in the territorial matrix. This network is connected by a set of linker molecules to other molecular in the matrix, including collagen type II fibers and the major proteoglycans. These networks are discussed separately.

Fibers with collagen type II as the main constituent *Collagen type II and collagen type XI*

The major fibrillar network in cartilage contains primarily collagen type II with a minor constituent of collagen type XI.¹⁵ A major feature of both these types of collagen is that the molecule forming the fibers is made up of three parallel, tightly associated polypeptide chains forming a very stable triple helix, the collagen molecule. It is extremely asymmetric—300 nm long and 1.5 nm in diameter. An amino acid quite unique for collagen is hydroxyproline, which is essential for stability of the molecule because of the hydrogen bonds formed to the hydroxyl group. Collagen type II is produced as a procollagen that does not form fibrils until the propeptides at both ends of the C- and N-termini are cleaved off (see Fig. e5.1). After this cleavage the molecules form fibers by interactions with other collagen molecules such that a large part of the surface of the molecule is engaged and the

collagen molecules are positioned so that they form a so-called quarter stagger arrangement in relation to one another.

The assembly process is regulated by a number of molecules in the matrix, including collagen type XI. It appears that the dimensions of the fiber formed depend on the relative proportion of collagens type II and XI, with the typical ratio being on the order of 50:1. This may depend on the presence of a central core of microfibrils of collagen type II and XI that direct assembly of the fiber.¹⁶

Collagen fibers in the superficial and deep layers of articular cartilage are different in dimension and direction. Thus, fibers in the superficial layer of articular cartilage are thin and run in parallel, whereas the thicker fibers in the deeper parts of cartilage run perpendicular to the surface. In the transition zone layer, fibers run at an angle (see Fig. e5.1).¹⁷ The organization can be seen as Benninghoff arcades on polarized light microscopy.

Collagen fiber formation is influenced by a number of matrix molecules, such as decorin, asporin, fibromodulin, COMP, and a special variant of an oversulfated chondroitin sulfate chain. In several of these cases the molecules are also retained bound at the surface of the collagen fiber. This is particularly evident for collagen type IX, which has part of the molecule extending out from the fiber. These molecules appear to have roles in providing sites for interaction with other matrix molecules, including fibers other than those to which the protein is bound (see Fig. 5.2).

An important feature of the collagen fiber network is that the interactions become sealed by covalent cross-link formation once the fibers are assembled outside the cell. This cross-linking depends on the oxidation of lysine and hydroxylysine residues by lysyl oxidase to provide an aldehyde function that forms a Schiff base with a neighboring lysine amino group. These are then rearranged to become stable pyridinoline groups that cross-bridge between the molecules and within the molecules of a fiber. These cross-links are important for mechanical stability of the collagen. Because they are not metabolized on degradation of the collagen, they eventually end up in urine and can be measured as indicators of collagen breakdown.¹⁸

PROTEOGLYCAN AGGREGATE STRUCTURE AND ORGANIZATION

Fig. 5.3 Depiction of the structure and organization of the proteoglycan aggregate. Also shown is a rotatory shadowing electron micrograph (courtesy of Matthias Mörgelin) of an aggregate isolated from tissue. The sites for degradation by the primary active ADAMTS-4 and ADAMTS-5 are indicated, as well as one site for cleavage of matrix metalloproteinase (MMP). CRP, C-reactive protein; CS, chondroitin sulfate; EGF, epidermal growth factor.

Collagen type XI

This fibril-forming collagen is an integral component of the fibers forming the main network in cartilage. Collagen type XI consists of a major triple-helical portion, similar in size to that of collagen types I and II, but in contrast to these collagens, the N-terminal propeptides are retained with the molecule incorporated into the fiber. Some reports have indicated that the retained N-terminal parts are exposed at the surface of the fibers, with collagen type II being the major constituent and the major triple-helical portion being located more centrally in the fiber.¹⁹ Collagen type XI together with collagen type II appears to form the initial assembly of microfibrils that regulate further assembly of the cartilage collagen fiber, at least in skeletal morphogenesis.¹⁶ Interestingly, collagen type XI forms cross-links to primarily other collagen type XI molecules.²⁰ There are examples of mutations in collagen type XI chains with ensuing major growth disturbances, thus indicating a role in cartilage growth and stability.²¹

Collagen type IX

This molecule is a member of the FACIT collagens (fibril-associated collagens with interrupted triple helices) and is found in tissue bound at the surface of the fibrils, with collagen type II being the major constituent. Collagen type IX contains three different α chains with three triple-helical domains (col1, col2, and col3), each surrounded by a noncollagenous domain (NC1, NC2, NC3, and NC4). The NC4 domain with its adjacent col3 triple helix protrudes from the fibers and is available for interactions with other molecules in the ECM, as schematically illustrated in Figure 5.2.²² Examples of such ligands are COMP and the tyrosine sulfate domain of fibromodulin. Collagen type IX often contains a chondroitin sulfate side chain bound at the NC3 domain. Its role in function of the collagen is not known.

Functionally, collagen type IX has been shown to interact with matrilins, COMP, and in particular, collagen type II. The collagen is actually covalently cross-linked to collagen type II in the fibers of adult individuals.²³ When

collagen type IX is added *in vitro* to fibril-forming systems of collagen type II, assembly and fiber formation are retarded.

Mutations in collagen type IX lead to severe growth disturbances, such as pseudoachondroplasia or multiple epiphyseal dysplasia. Some of these disturbances are similar to those with a mutated COMP molecule, which is of special interest in view of the high-affinity interaction that this protein shows with all four NC domains of collagen type IX. Furthermore, early lesions of articular cartilage similar to those found in osteoarthritis develop in mice with knockout of collagen type IX.²⁴

Molecules regulating collagen fiber assembly

The dimensions and orientation of collagen fibers in tissue vary between different layers of articular cartilage. Moreover, fibers in the territorial matrix close to cells are thinner and have similar dimensions in different layers of cartilage. In contrast, fibers in the interterritorial matrix are thicker and have larger and more variable diameters in the deeper layers. This regulation of fiber diameter is achieved by a number of macromolecules that bind to collagen. The exact role of individual molecules in achieving the final dimensions and direction of the fibers is not clear, although there are a number of examples in which inactivation of individual genes of the involved proteins leads to altered dimensions of collagen fibrils. It is notable that asporin, like decorin, inhibits collagen fiber formation and that levels of these protein are selectively very high in superficial parts of the articular cartilage, where collagen fibers are thin.²⁵

The extremely long half-life of collagen type II, in excess of 100 years,^{9,26} indicates that very little collagen is eliminated over the life of an individual; however, at the same time, fibers defective as a result of fatigue have to be repaired. It is possible that the very variable dimensions of the fibers in the interterritorial matrix result from adding newly synthesized collagen molecules at the fiber surface and thus gradually increasing the diameter to provide mechanical stability.

A number of molecules bound at the surface of collagen fibers are likely to prevent further accretion of collagen. It is plausible that these molecules will need to be removed before new collagen molecules can be added to a fiber for remodeling or repair.

It appears that even though the collagen itself does not turn over, molecules on the fiber's surface are continuously removed and replenished.

Molecules with putative roles in regulating fibril formation are found among those that can bind collagen *in vitro*.

Cartilage oligomeric matrix protein

COMP is a molecule primarily found in cartilage, where it is quite abundant at a concentration of around 0.1% of the tissue's wet weight. The molecule is made up of five identical subunits, each with a molecular weight of around 87,000 Da. The five subunits are held together by a coil-coiled domain close to the N-terminal end, and disulfide bridges further stabilize the binding. The subunits are made up of several modules, including some binding calcium. At the C-terminal end there is a globular domain that is involved in interactions with other proteins in the matrix. The molecule can be viewed as a bouquet of tulips tied together at their stalks (see Fig. 5.2).²⁷

COMP, also referred to as thrombospondin-5, is a member of this family of proteins. Cartilage also contains other thrombospondins that share the same properties, with thrombospondin-1 and thrombospondin-4 being particularly abundant. These thrombospondins, however, contain an extension beyond the coiled-coil domain in the N-terminal that has a heparin-binding motif, in this manner adding additional interacting sites. Thrombospondin-4 contains five identical subunits, whereas thrombospondin-1 contains only three.¹

The three-dimensional structure of the C-terminal domain of thrombospondin-1 has been resolved, and its organization has been found to be stabilized by a large number of calcium ions.²⁸ Because the C-terminal domain of the various thrombospondins shows a great deal of conservation, it is likely that its structure is similar in all five members of the family.

COMP has been shown to bind to collagens type I and II,¹ where each individual C-terminal globular domain provides high affinity in the nanomolar range. Four binding sites are evenly distributed along the collagen molecule. There is one at each end and two positioned along the filament such that the distance is similar between the four binding sites. Even though each COMP molecule has five identical binding sites, an individual molecule can engage only one binding site on each collagen molecule and not span the distance between two such sites. Therefore, each COMP molecule has the potential to bind to five different collagen molecules. The quarter stagger arrangement of collagen in the fiber and the fact that a pentameric microfibril unit appears to exist²⁹ may relate to the four similarly spaced collagen binding sites in the molecule. COMP will accelerate and provide faster collagen fibril formation *in vitro*. It appears that this effect is mediated by the COMP molecule bringing together several collagen molecules to facilitate their interactions in the forming fiber. The COMP molecule does not remain bound directly to the surface of the forming fiber. The molecule thus appears to function as a catalyst to enhance fibril formation.

In the cartilage of growing individuals and notably in the growth plate, COMP is primarily localized close to the cells in the territorial matrix, where it may have a role in stimulating collagen fibril formation.³⁰

COMP has the ability to interact with all four NC domains of collagen type IX with similar high affinity in the nanomolar range. The interaction is mediated via the C-terminal globular domains (see Fig. 5.2).

In adults, COMP is localized primarily in the interterritorial matrix and may be bound to collagen type IX or one of the matrilins, which in turn bind to the surface of the collagen fiber (see Fig. 5.2). The role of COMP in adult cartilage appears to be stabilization of the collagen fiber network.

Mutations in the calcium-binding domain of COMP, as well as in the C-terminal domain, have been shown to lead to severe growth disturbances in the form of pseudoachondroplasia or multiple epiphyseal dysplasia. A feature of these conditions is that material retained in the endoplasmic reticulum of chondrocytes contains both COMP and collagen type IX.³¹

On the other hand, the COMP-null mouse shows no detectable alteration in phenotype.³² It is possible that other molecules compensate for the lack of COMP function in such mice.

COMP is significantly upregulated in early stages of osteoarthritis, even long before diagnosis, in an apparent attempt at repair. At the same time the protein already deposited is cleaved and released from the tissue. Indeed, assay for such fragments released into body fluids has been used to measure altered cartilage metabolism as a biomarker for arthritic disease.³³

Decorin

Decorin was the first molecule in the leucine-rich repeat (LRR) protein family to be cloned and sequenced. This family of molecules in the ECM

contains four subclasses with a total of 12 members, all of which appear to share the function of binding to collagen (Fig. e5.2).¹

One functional domain of these molecules is a central LRR region, where residues, particularly leucine, are found at conserved locations in each repeat of some 25 amino acids, albeit somewhat variably long. Most of these molecules have 10 to 11 such repeats, and the entire domain contains a disulfide loop structure at each end. One subgroup contains molecules with only six repeats.

For further details on decorin, see ExpertConsult.com.

Decorin binds tightly to the fibril-forming collagens with a K_D in the nanomolar range. Binding is close to the C-terminus of the collagen as shown for collagen type I. Binding occurs via the LRR region and particularly involves repeats 4 and 5.¹ The critical sequence has been identified as SYRIADTNIT.³⁶

Via its binding to collagen, decorin inhibits the formation of collagen fibers *in vitro* in a dose-dependent manner. Accordingly, mice lacking decorin as a result of knockout technology have irregular collagen fibers with increased diameter, particularly prominent in skin.³⁷ They do not show increased early joint pathology, thus indicating that other molecules may compensate for the lack of decorin in articular cartilage.

Decorin is bound to collagen fibers in tissue, with the glycosaminoglycan chains being free to interact with other molecules. Thus, decorin can cross-bridge to neighboring collagen fibers, as well as to other molecules in the local environment (see Fig. 5.2).

Fibromodulin and lumican

Fibromodulin and lumican belong to the same subclass of LRR proteins but with a gene arrangement distinct from that of decorin. Other members of this subgroup are keratocan, osteoadherin, and PRELP. All these molecules except PRELP contain tyrosine sulfate residues in the N-terminal extension. Notably, the number of such sulfate residues is variable both with regard to the relative proportion of candidate tyrosine residues that are sulfated within a given molecule and with regard to the number of such tyrosine residues that may carry a sulfate. One extreme is represented by fibromodulin, which contains up to nine sulfate residues; osteoadherin contains up to eight, lumican up to four, and keratocan only one.³⁸ PRELP, in contrast, contains a cluster of basic residues that contribute heparin-binding activity for this molecule.³⁹

Collagen binding of fibromodulin has been studied extensively. It has been shown that the molecule inhibits fibril formation *in vitro*. The fibromodulin-null mouse shows altered collagen fibril dimensions, particularly apparent in the tail tendon. Unexpectedly in view of the inhibitory effects observed *in vitro*, the tendon contains a much larger number of thin fibrils. An explanation appears to be a higher abundance of the related lumican molecule, which could be shown to bind to the same site on the collagen, albeit with somewhat lower affinity. It thus appears that lumican may guide early events in fibril formation. The molecule may then be completed away by fibromodulin to introduce a different function. Because the mRNA levels and therefore synthesis of lumican were lower in the null mouse, it appears that the higher levels of this protein were caused by retarded elimination apparently secondary to lack of competition by fibromodulin.¹

These findings illustrate that fibril formation takes place in many steps involving a set of different molecules with different roles.

Fibromodulin is also present on collagen fiber in tissue, where it is bound in the gap region.¹ It appears to be bound via its protein core with exposure of a keratan sulfate chain, as well as the tyrosine sulfate domain, which then become available to interact with PRELP and the NC4 domain of collagen type IX located on neighboring fibers. Such interactions are important for the stability and properties of the collagen network.

Fibromodulin is a target in joint disease. In a model of articular cartilage destruction caused by stimulation with IL-1 in explant culture, we have been able to show that fibromodulin is degraded after aggrecan and that the molecule is initially cleaved by MMP-13 to release almost the entire N-terminal tyrosine sulfate domain while the remainder of the molecule is initially retained in the tissue, probably bound to the collagen.⁴¹ This loss of the anionic domain is likely to alter the properties and interactions of fibromodulin. At the same time, MMP-13 can release the entire NC4 domain of collagen type IX from cartilage.⁴² This results in loss of function, with impaired noncovalent associations between collagen fibers most likely leading to impaired maintenance of structure and function of the cartilage. This may represent a central mechanism in the swelling and surface fibrillation observed in early osteoarthritis.

It is of interest to note that the particular fragment retained in the tissue is found only in pathologic and not in normal tissue, although there is continuous turnover of matrix constituents in response to altered load,

Fig. e5.2 Note the variability in the N-terminal domain between molecules, which shows negatively charged groups of different character (glycosaminoglycan, tyrosine sulfate, polyaspartate, or a cluster of basic amino acids). The C-terminal extensions of two members have distinct features. The dimeric form found for decorin and biglycan on x-ray crystallography is illustrated schematically. CHAD, chondroadherin; ECM, extracellular matrix; LRR, leucine-rich repeat; OSAD, osteoadherin.

Decorin—additional information

One variable of almost all the molecules in the family is an N-terminal extension of generally less than 20 amino acids, which may contain a variety of substituents (see Fig. e5.2). Some of the molecules also have a C-terminal extension. There is also variation in glycosylation of the repeat domain, which usually contains a few N-linked oligosaccharides. In some of the small LRR proteins, such as fibromodulin and lumican, some of the oligosaccharides may contain a variably long array of 6-O-sulfated lactosamine repeat disaccharides (see Fig. 5.3) extended to form the glycosaminoglycan keratan sulfate.

The three-dimensional structures of decorin³⁴ and biglycan³⁵ have been resolved by x-ray crystallography. These molecules contain one (decorin) or two (biglycan) glycosaminoglycan chains bound at the N-terminal extension. These chains are chondroitin sulfate or dermatan sulfate, depending on the tissue, though very similar between the molecules in a given tissue. In articular cartilage the chain is a low-epimerized dermatan sulfate in which a few of the glucuronic acid residues have been epimerized to iduronic acid, thereby increasing its structural variability. This glycosaminoglycan has the capability of specific interactions with other molecules in the matrix, including binding other dermatan sulfate chains.¹

Based on the x-ray crystallographic data presented, the LRR family of molecules forms a curved structure in which two molecules form a dimer in the crystals that overlap in opposite directions in about 50% of their length such that the N-terminus of one molecule is located in the middle of the curved domain of the other. Support for such a dimeric structure was obtained by other techniques such as gel filtration with on line dynamic light scattering.³⁴ Electron microscopy indicates that decorin and biglycan, as well as chondroadherin, may also exist in a monomeric form at very low concentrations (Mörgelin and Heinegård, unpublished work).

The presence of the proteoglycan as a monomer or a dimer has specific relevance for interactions and functions. Thus, a monomeric molecule has only one of each interacting site, whereas a dimer may exhibit two of each binding site.

Fibromodulin and lumican—additional information

The function of this domain with clustered tyrosine sulfate residues is becoming clearer. The domains in fibromodulin and osteoadherin mimic heparin in many interactions and bind growth factors (e.g., fibroblast growth factor-2 [FGF-2]), cytokines (e.g., oncostatin M and IL-10), MMPs (e.g., MMP-13 for fibromodulin), and a number of matrix proteins via their heparin-binding domains (e.g., PRELP and chondroadherin).⁴⁰ Thus, the fibromodulin on a collagen fiber appears to extend its tyrosine sulfate domain, which can bind to molecules with cationic domains. One such charged structure is the NC4 domain of collagen type IX, which has been shown to interact with the anionic N-terminal extension of fibromodulin,⁴⁰ as schematically outlined in Figure 5.2.

All the molecules in this family appear to bind to collagen via their LRR domain with dissociation constants ranging from 1 to 10 nM.¹ Only in a few cases has it been established exactly where along the collagen that the LRR protein binds.

including removal of damaged components. This normal turnover appears to involve different mechanisms of cleavage.

Other leucine-rich repeat proteins

PRELP is distinguished by having a basic, heparin-binding N-terminal domain.⁴³ This mediates binding to molecules with heparan sulfate side chains, including perlecan and cell-surface syndecan and glypican. Simultaneously, the protein binds via its LRR domain to two sites on fibril-forming collagen types I and II. Thus, the molecule has the potential to bridge from the collagen network back to the cell surface. It consequently has the potential to provide feedback to cells on the condition of the matrix. Little is known of alterations in PRELP in joint disease. An interesting observation is that the isolated heparin-binding domain of PRELP binds to osteoclast precursors via cell-surface proteoglycans. The peptide becomes internalized and translocates to the nucleus, where it inhibits nuclear factor- κ B (NF- κ B), the target of receptor activator of NF- κ B ligand (RANKL), an important stimulator of osteoclast development. The effect of the peptide is thus to inhibit osteoclast formation. Indeed, PRELP has been used to prevent the development of osteoporosis in ovariectomized mice.⁴⁴

Chondroadherin is a cell-binding protein that forms its own subclass. The protein is further discussed below.

Asporin is a close relative of decorin but differs in having a variably long polyaspartate sequence in the N-terminal end. The number of aspartate residues varies between individuals.⁴⁵ It has been demonstrated in studies of several cohorts of individuals in Asia that osteoarthritis is overrepresented in individuals with 14 such residues versus those with 13 residues in the asporin N-terminal structure.⁴⁶ In a different study from the United Kingdom, no such pronounced relationship could be discerned, thus indicating that other factors are also involved.⁴⁷ One function of the polyaspartate sequence appears to be calcium binding, for which there may be a difference between the 13 and 14 aspartate variants.⁴⁸ At the same time, asporin binds to collagen at the same sites that decorin does,⁴⁸ which can facilitate its fixation to collagen fibers in the tissue. The molecule may thus have roles in regulating mineralization, which is relevant to the development of osteoarthritis. Asporin, like decorin, biglycan, and fibromodulin, appears to bind transforming growth factor- β (TGF- β).

There is a set of LRR proteins with only six repeats.¹

Heparin/heparan sulfate

A glycosaminoglycan not prominent in cartilage is heparan sulfate, which has structural features overlapping those of heparin. Heparan sulfate is found as side chains of extracellular perlecan (discussed below), which has a very large protein core with several domains interacting with a number of other proteins in the ECM. The proteoglycan contains an N-terminal domain with some three glycosaminoglycan chains and a C-terminal domain with up to two chains. These chains may be heparan sulfate or chondroitin sulfate (discussed later).

Heparan sulfate contains two types of disaccharide repeats consisting of either a glucuronic acid and an N-acetylglucosamine or an iduronic acid and an N-acetylglucosamine. The hexosamine carries an O-sulfate group, and some of the residues have an additional N-sulfate instead of the N-acetyl group. Also, the uronic acid may be sulfated, usually in its 2 position. Thus, there is extensive variability in the building blocks, which are then assembled in variably long stretches with different repeat stretches of low- and high-sulfated residues.

Other heparan sulfate-containing proteoglycans are found at the cell surface of the chondrocyte. These include four different syndecans,⁴⁹ which contain a domain intercalated in the cell membrane, and some six glypicans, which are joined via a glycosylphosphoinositide linkage.⁵⁰ The syndecans contain an intracellular signaling domain, and as discussed below, they are involved in a number of cell reactions, and bound molecules can induce signal transduction.

Fibers/networks with collagen type VI as the main constituent

There is a different fibrillar network in cartilage with a more restricted distribution in tissue. It has collagen type VI as a major constituent and is primarily present in the territorial matrix surrounding the cells (see Fig. 5.1).

Collagen type VI

Collagen type VI has a distinctive network of beaded filaments. This molecule contains three different α chains with a central triple-helical domain flanked by globular domains. The N-terminal portion, particularly the α_3 (VI) chain, contains nine von Willebrand factor A (vWFA)-like repeats. In addition, the

C-terminal portions of all three chains contain two vWFA repeats, as well as other motifs with less clear functions. The vWFA domain is found in many proteins, where it is involved in protein-protein interactions.⁵¹

While still within the cell, two collagen type VI molecules associate in an antiparallel fashion such that the dimer is flanked by the N-terminal domains and the two C-terminal domains are placed so that they form two interior globular structures along the filament formed by the two triple helices. Two such dimers associate laterally to form a tetramer, with the globular domains at each end representing a pair of the vWFA-rich globules. Internally in the triple-helical central filament are found the two globular structures representing the C-terminals.⁵¹ The tetramer is secreted from the cell, and its N-terminal structures lay the ground for further associations with fibrils involving both end-to-end and side-to-side interactions. This assembly process appears to be governed by other molecules, particularly members of the LRR protein family.

Biglycan and decorin

Biglycan and decorin both bind with high affinity to the collagen type VI N-terminal domain, independently of their glycosaminoglycan side chains. This binding is a prerequisite for formation of the collagen type VI beaded filament network *in vitro*. Regulation of collagen type VI assembly also depends on the presence of the chondroitin/dermatan sulfate side chains, where the two present in biglycan provide more efficient filament formation than the single chain in decorin does. The two closely related proteoglycans appear to bind to the same site, which interestingly does not seem to involve the triple-helical domain in this collagen.⁵²⁻⁵⁴

Matrilins

Cartilage matrix protein (CMP; matrilin-1) was the first of the four matrilins identified. These proteins (for references, see Klatt and colleagues³⁹) contain vWFA domains. Matrilin-1 has two such domains in each of the three identical subunits with a molecular mass of around 50,000 Da; matrilin-3, with four subunits, has only one such domain.

Matrilin-1 and matrilin-3 are quite restricted to cartilage and show similar distribution between different tissues, whereas the others have a more general distribution. Interestingly, matrilin-1 is even further restricted and not found in articular cartilage and intervertebral disks, but it is particularly prominent in tracheal cartilage. The protein is present in the more immature cartilage of the femoral head during earlier phases of development and can be seen in the early bone anlagen. Its role in cartilage is becoming clearer, and data indicate roles in collagen network function and integrin binding (for references, see Klatt and colleagues³⁹). Its two vWFA homology domains (only one in matrilin-3) may mediate the ability of the protein to bind to collagen. Matrilin-1 was initially isolated because of its apparent ability to bind to aggrecan.

Mutations in matrilin-3 can induce multiple epiphyseal dysplasia or pseudoachondroplasia with skeletal malformations, similar to those caused by mutations in the interacting partners of the proteins, such as collagen IX.⁵⁶

Matrilin-1 can be isolated from cartilage as a mixed polymer that contains subunits of matrilin-1, as well as matrilin-3. The functional significance of this heterocomplex is not understood.⁵⁷

A module cross-linking to other matrix constituents

Decorin and biglycan appear to also have roles in the completed network. Collagen type VI isolated from chondrosarcoma cartilage-like tissue contains biglycan or decorin bound at the N-terminal globules. The proteoglycan in turn has a bound member of matrilin-1, matrilin-2, or matrilin-3. This interaction is tight with a dissociation constant on the order of nanomolar. The matrilin, in turn, binds to a procollagen type II molecule or a completed collagen fiber. Alternatively, matrilin can bind to an aggrecan molecule (see Fig. 5.2).⁵⁴ Thus, collagen type VI seems to be a center in a scaffold that binds to the other major networks in the matrix. Collagen type VI is found only in the territorial matrix closer to cells and is absent from the interterritorial matrix at some distance from the cells. Information on alterations in collagen type VI in joint disease is limited, but it is important to note that the protein is found to be particularly enriched in tissue subjected to load.

MOLECULES INTERACTING AT THE CELL SURFACE AND MODULATING CHONDROCYTE BEHAVIOR

It is important to realize that chondrocytes have the ability to both degrade the matrix and replenish lost molecules with new constituents in a process

Other leucine-rich repeat proteins—additional information

Such proteins include epiphykan, mimecan, and opticin. In addition, these molecules appear to have the ability to bind collagen. They all contain N-terminal extensions carrying glycosaminoglycan chains (epiphykan), tyrosine sulfate residues (mimecan), or *O*-glycosidically linked oligosaccharides (opticin) (see Fig. e5.2). Mimecan has also been named osteoglycin. There is limited knowledge on alterations of these proteins in joint disease. They do show interesting differences between different types of cartilage. Mimecan is present in articular cartilage, menisci, and intervertebral disks but virtually absent in nasal and tracheal cartilage, whereas epiphykan is prominent in the latter cartilage and absent from the others. Opticin is particularly prominent in connective tissues other than those of joints.

of remodeling the tissue in response to material fatigue or to altered load. The cells are guided in this endeavor by receptors at their surface that recognize specific molecules in the matrix (see Fig. 5.2). Binding elicits specific signals that will either induce cellular spreading and migration by engaging the cytoskeleton or lead to alterations in transcription and protein synthesis. Other stimuli that will affect cells include mechanical forces, which provide signals that crosstalk with those from other interactions at the cell surface. Indeed, some data indicate that some of the signals elicited by mechanical load involve integrins.⁵⁸

Integrin binding proteins

The integrins contain an α chain noncovalently bound to a β chain. The cells in connective tissues contain either a β_1 or a β_3 chain in conjunction with one of many α chains. The various integrins have different preferred ECM ligand proteins.⁵⁹ As an example of the organization of integrins, members of one such family with four members bind to collagens. They contain a β_1 chain in combination with either an α_1 , α_2 , α_{10} , or α_{11} chain. These various integrins have different tissue distributions such that the one with α_{10} appear to be unique to cartilage whereas the others have more ubiquitous distributions. Their binding to collagen may elicit different responses and result primarily in either altered production of enzymes degrading the matrix or production of building blocks such as collagen molecules.

A number of factors limit our ability to discern which integrins are present on chondrocytes in tissue. One factor is limited accessibility by the antibodies used and another is changes in the presence of integrin during the long procedure for cell isolation. Thus, the current information on the presence of integrins at the cell surface is variable. It is likely that a number of integrins change their expression on chondrocytes in normal and in pathologic tissue in response to environmental factors.

Many of the molecules binding to integrins are not unique for cartilage. The collagen-binding integrins do not appear to be specific for a particular fibril-forming molecule. One exception is chondroadherin. This protein appears to be restricted to cartilage and can bind $\alpha_2\beta_1$ integrin, though not other integrins containing the same β chain.

Chondroadherin

Chondroadherin is a member of the LRR protein family that is in its own subclass. This protein differs from other LRR family members in that the C-terminal cysteine loop is double and the protein has a short C-terminal extension of basic amino acids. The protein has no N-terminal extension. Chondroadherin specifically binds to cell-surface $\alpha_2\beta_1$ integrin^{1,60} via a sequence in one of its C-terminal disulfide loops. Interestingly, integrin binding elicits signals that do not induce cell spreading. The very C-terminal short extension peptide of chondroadherin contains a different cell-binding sequence that engages the heparan sulfate chains of cell-surface proteoglycans, notably syndecans.⁶¹ Binding leads to cell spreading, as well as enhanced integrin activity. The combined engagement of integrins and heparan sulfate leads to cells forming focal adhesion complexes.

Chondroadherin is present in articular cartilage but virtually absent from menisci. The protein is particularly enriched during growth in the prehypertrophic zone of the growth plate where cell multiplication is slowed, in line with its *in vitro* effects on cell behavior. Interestingly, the protein appears to be lost early in the process of joint damage in osteoarthritis (unpublished observations).

Fibronectin

Fibronectin⁶² is present in most tissues and can actually form its own fibrils, which appear to have roles in guiding matrix assembly and cell migration. The protein contains two identical subunits held together by disulfide bonds close to their C-terminal end.

Fibronectin contains a collagen-binding domain with preference for denatured collagen (gelatin). There are integrin-binding domains in which the RGD (arginine-glycine-aspartic acid) sequence represents the classic motif of integrin binding. This motif in fibronectin preferentially binds $\alpha_5\beta_1$ integrin, although $\alpha_v\beta_3$ integrin can also interact. Fibronectin also has other integrin-binding domains.⁶³

Another motif is represented by the two heparin-binding domains on each subunit, each some 20 kDa. These domains can interact with heparan sulfate proteoglycans at the cell surface, including syndecan, which also represent signaling molecules.⁶⁴

Although the details are not known, fragments of fibronectin (e.g., those containing either of the heparin-binding domains), when added to cartilage in explant culture, as well as injected into the joint, will stimulate chondrocytes to produce proteases and induce cartilage breakdown.^{65,66} In contrast,

the intact fibronectin molecule will not have such effects on cells. It is possible that fragmentation of fibronectin is one mechanism for propagating joint destruction in disease. The active fragments have not yet been identified in body fluids.

Fibronectin is already upregulated in articular cartilage at very early stages of osteoarthritis in many species, including humans.¹³ The functional consequences of this upregulation are not known but may represent part of an attempt at repair. A result is further availability of fibronectin, which may be fragmented to further increase tissue degradation.

Collagen and the discoidin domain 2-containing receptor

Collagen has an additional cell receptor for discoidin domain receptor 2 (DDR-2). This receptor has been shown to be upregulated in mice in which osteoarthritis is developing. DDR-2 will bind collagen type II, thereby inducing upregulation of MMP-13 production.⁶⁷ Exposure of collagen type II may be enhanced by removal of proteins bound at the fibrillar surface, thus making the molecule available for interactions.

Hyaluronan

Hyaluronan is an extremely long glycosaminoglycan chain that is distinct from all the others in that it is not bound to a protein core. It does not contain any sulfate groups. The backbone is made up of one to several thousand repeating disaccharides of glucuronic acid and *N*-acetylglucosamine. As discussed earlier, hyaluronan specifically binds to a domain in aggrecan that is essential for the formation of aggregates.

Hyaluronan also interacts with specific cell-surface receptors. These receptors are CD44 molecules⁶⁸ that interact with a minimally long hexasaccharide sequence of the polymer. The interactions with hyaluronan are important for organizing the pericellular environment and providing signals to the cell. CD44 occurs in many different splice forms with variable presence on different cells, but a role for such variability in joint disease is unclear. Another receptor for hyaluronan is RHAMM,⁶⁹ also a signaling receptor and, like CD44, present on a variety of cells.

Ligands for heparan sulfate/syndecans

In addition to the heparin-binding domains present in fibronectin, various other matrix proteins contain such domains. Examples are most members of the thrombospondin family, with the exception of COMP, many MMPs, CILP, and PRELP.¹ As discussed above, isolated heparin-binding domain fragments can have variable effects on, for example, cells, depending on their fine structure. Effects range from inducing cartilage breakdown *in vitro* and *in vivo* to decreasing bone breakdown by targeting osteoclast precursors.

Interestingly, as discussed earlier, the N-terminal tyrosine sulfate domain of fibromodulin can mimic heparin in many interactions and bind other proteins to crossbridge networks, as well as sequester growth factors.

OTHER MOLECULAR FUNCTIONS

In joint disease, inflammation is a frequent component causing pain and limiting function. The inflammation is usually chronic, and one issue is whether components from cartilage can propagate the inflammatory activity. It is a long-standing observation that when cartilage is removed in joint arthroplasty, the inflammation recedes, thus indicating that factors released from the tissue have a role in propagating inflammation.

It has been shown that some patients with rheumatoid arthritis have circulating antibodies to collagen type II. Furthermore, an arthritis condition can be elicited by injecting mice and rats with collagen type II (collagen-induced arthritis). The disease can be transferred by antibodies to specific collagen type II epitopes.⁷⁰ It is hence possible that antibody binding activates complement and inflammation.

More recent findings indicate that matrix proteins may activate innate immunity. Fibromodulin has been shown to be as active as immune complexes⁷¹ in activating the classical pathway of complement, although it does not bind to the same site. Fibromodulin binds to the head domains of C1q rather than to the triple-helical stalk region with ensuing deposition and activation of C4 and C3.

Interestingly, fibromodulin can also recruit factor H by binding to a different site than that for C1q and thereby inhibit further activation of the complement cascade. Whether different fragments released in disease will have different roles in complement activation remains to be shown.

In other experiments it has been demonstrated that biglycan can also bind the triple-helical stalk of the complement factor C1q and in so doing inhibit activation of the classical pathway of complement. It appears that other LRR proteins such as biglycan and decorin can also bind factors involved in regulating the complement cascade. One example is a tight interaction with C4BP having a role in regulating complement activity.⁷²

COMP is a potent activator of the alternative pathway via its C-terminal globular domain. Interestingly, this activity can be observed in synovial fluid from subjects with both osteoarthritis and rheumatoid arthritis, as well as in blood in the form of COMP-C3b complexes created between the activator COMP and the C3b fragment formed.⁷³

Binding and sequestering growth factors in the extracellular matrix

The ECM of cartilage contains a number of factors that are sequestered and thereby bind to specific interaction partners. On degradation of the matrix one can envisage that these factors are released and affect cellular activities. In particular, a number of growth factors have been found to have the capacity to bind to matrix proteins.

Transforming growth factor- β

TGF- β has been shown to bind to a number of matrix proteins, and binding to some members of the LRR protein family has been investigated in particular. All three TGF- β variants bind to bacterially expressed decorin, biglycan, and fibromodulin, as well as to these proteins with the full range of posttranslational modifications. More recently, there are indications that asporin can also bind TGF- β . It has been demonstrated that active TGF- β is released from decorin on treatment with MMP-3. Indeed, cartilage contains substantial amounts of TGF- β , which has been extracted and purified from the tissue.

Fibroblast growth factor

Some matrix proteins contain heparan sulfate side chains, which are likely to bind growth factors within the FGF family. In the case of syndecan at the cell surface, these side chains appear to be involved in presenting the growth factor to its receptor.⁷⁴

Other molecules in the extracellular matrix

Perlecan was found to have a central role in cartilage development when a mouse with the gene inactivated was developed. Most of these mice die during early development as a result of problems with the heart and major blood vessels, but those that survive until birth show major growth disturbances with an extensively altered growth plate lacking a large proportion of the collagen fibers.⁷⁵ Further studies have revealed that chondroitin sulfate side chains specific for perlecan can actually accelerate and catalyze collagen fiber formation.⁷⁶

FRAGMENTS OF MATRIX PROTEINS RELEASED DURING CARTILAGE BREAKDOWN AS MOLECULAR INDICATORS OF DISEASE

In processes resulting in destruction of cartilage tissue, proteolytic enzymes degrade ECM proteins. Some of the fragments formed will no longer be retained in the tissue but are released to surrounding body fluids. By using sensitive immunoassays such fragments can be quantified in synovial fluid or serum. This so-called molecular marker technology (biomarkers) is intended to provide new means of assaying ongoing active processes in articular cartilage. With further development such techniques may be used in diagnosis, for estimation of the activity of the tissue-destroying process, to document effects of therapeutic intervention, and most importantly, to discover processes during the early stage before clinical symptoms become apparent. One example is the demonstration that COMP can be used to identify patients who will have the most extensive joint destruction in both osteoarthritis and rheumatoid arthritis.^{33,79} Also, a number of collagen fragments created by cleavage with collagenases, as well as by subsequent gelatinase activity, have been used to monitor disease.^{80,81} With further development of the technology we hope to be able to identify indicators specific to a particular pathologic process in a given tissue. Thus, it should be possible to identify the activity of a process in the meniscus on the one hand and activity in cartilage on the other.

As discussed earlier, some of the fragments released will activate immune responses with the potential to further enhance disease activity.

Other molecules in the extracellular matrix—additional material

GP-39 is a protein upregulated in osteoarthritis. It shares homology with a chitinase, but the true activity of the protein is not known.⁷⁷ GP-39 is additionally expressed in a number of other tissues, particularly in disease.

Cartilage matrix also contains a number of proteins that are made elsewhere and are normally found primarily in the circulation. There is a preference for certain proteins, and low-molecular-weight basic proteins (e.g., lysozyme) in particular appear to bind to the matrix.⁷⁸ Whether these molecules contribute specific functions is not known.

Bone structure and function

■ DAVID B. BURR ■ TERESITA BELLIDO ■ KENNETH E. WHITE

- Bone is organized differently and for different functions at the organ, tissue, and molecular levels.
- Noncollagenous proteins function as structural support in the bone matrix and regulate mineral deposition, crystal growth, and cell attachment.
- Bone mineralization is effected through hormonal action (fibroblast growth factor 23 [FGF-23]) as well as through the bioactivity of intracellular and secreted matrix proteins with emerging roles (dentin matrix protein-1, FAM20c, and matrix extracellular phosphoglycoprotein).
- Growth factors including insulin-like growth factor 1, the autocrine/paracrine FGFs, and transforming growth factor- β play key roles in bone growth and structure.
- Osteoclasts are the primary bone-resorptive cells and originate from precursors of the hematopoietic lineage upon stimulation with receptor activator of nuclear factor- κ B ligand (RANKL) and macrophage colony-stimulating factor.
- The rate of osteoclast generation determines the extension of the bone-remodeling unit, whereas the life span of osteoclasts determines the depth of resorption.
- Osteoblasts are responsible for bone formation and originate from mesenchymal progenitors that also give rise to chondrocytes, muscle cells, and adipocytes.
- Osteocytes form a network that senses mechanical and hormonal environmental cues and orchestrates the function of osteoblasts and osteoclasts.
- Osteocytes produce and secrete factors (sclerostin/Sost, RANKL, osteoprotegerin) that affect other bone cells by paracrine/autocrine mechanisms and also secrete hormones (FGF-23) that affect other tissues by endocrine mechanisms.
- Four dynamic processes—growth, modeling, remodeling, and repair—control skeletal development and adaptation, defined by the relationship of bone resorption and bone formation to each other.

INTRODUCTION

Bone is a complex natural composite material that undergoes millions of loading cycles during a lifetime without failure. Its structure is hierarchical, being organized differently at the organ (whole bone), tissue (material), and molecular (collagen-mineral) levels.

The mechanical functions of bone are the most widely recognized and are often described in terms of strength and stiffness. Although strength and stiffness are important, bone is particularly effective at dissipating energy that could cause a fracture over repeated cycles of loading. Beyond its mechanical function, the marrow cavity and the porous trabecular bone in the ends of long bones and in the vertebrae and iliac crest are regions in which red blood cells are formed and stored. Bone is in fact a primary blood-storing organ. Additionally, bone is the body's primary storehouse of calcium and phosphorus; 99% of the body's calcium is stored in bone. These minerals are necessary for the proper function of a variety of systems in the body and are essential for enzyme reactions, blood clotting, the proper function of contractile proteins in muscles, and the transmission of nerve impulses.

ORGANIZATION OF BONE

Macroscopic (organ) level

Bone at the organ level consists of the diaphysis (shaft), the metaphysis and the epiphysis (Fig. 6.1). In the long bones of growing children, the growth plate separates the epiphysis from the metaphysis. The primary component of the diaphysis is cortical or compact bone. The haversian canals in cortical bone create a porosity of about 3% to 5%, although this increases in older age and with osteoporotic changes to the skeleton. Compact bone is also found surrounding the spongy bone of the vertebral body and in the skull. It is very strong and provides both support and protection.

Cancellous (trabecular or spongy) bone is found in the metaphyses of the long bones and in the vertebrae, surrounded by cortical bone. During growth, the primary spongiosa is composed mostly of disorganized woven bone, or primary lamellar bone surrounding a core of calcified cartilage. It is separated from the remodeled, more highly oriented secondary spongiosa by an arbitrary boundary. The secondary spongiosa reflects patterns of stress and functions largely to funnel stresses to the stronger and more massive cortical bone. In regions beneath joint surfaces it also attenuates forces generated by mechanical loading and may protect the joint surface from loading-related trauma. The cancellous bone itself is composed of plates and rods of bone, each about 200 μ m thick, with a porosity of about 75% to 85%. The marrow in the spaces between the trabecular struts are regions in which red blood cells are formed (red marrow). In osteoporosis, the differentiation of cells in the bone lineage can be partly diverted to adipocytes, and the marrow becomes more fatty (yellow marrow). Because cancellous bone has a large surface area in contact with vascular marrow, it is ideal for the long-term exchange of calcium ions. In osteopenia, regions of cancellous bone are affected first. This is why the vertebral column, which is mainly composed of cancellous bone, is affected earlier and more severely in osteoporosis than even the femoral neck and hip.

Microscopic (tissue) level

At the microstructural level, bone is organized differently for different functions (Fig. 6.2). In humans bone tissue can be divided into three broad categories based partly on the arrangement of the collagen fibers and partly on whether it has replaced preexisting bone: (1) woven bone, (2) primary bone, and (3) secondary bone.

Woven bone is characterized by randomly oriented collagen fibers, which tend to be smaller in diameter than those in more highly organized primary or secondary bone. Woven bone is not lamellar, is very porous, and may become highly mineralized. Woven bone can be deposited *de novo* without any bony or cartilaginous substrate or anlage, but it can also be formed as part of the process of endochondral ossification, either at the growth plate during development or during fracture repair. Woven bone proliferates rapidly because it has a large cell-volume ratio, which makes its role in fracture repair ideal. It is often found associated with osteosarcoma, probably because of proliferation especially of the cellular periosteum. The function of woven bone is primarily mechanical, rapidly providing both temporary strength and scaffolding upon which lamellar bone may be deposited. However, it can also be associated with pathologic processes that involve inflammatory cytokines.

Primary bone must be deposited on a preexisting substrate and is organized into lamellar layers. Because of this, trabecular plates, which are composed mainly of primary lamellae, cannot be replaced once they are perforated. This accounts for the loss of trabeculae with age and is part of

Fig. 6.1 At the organ level, bone consists of compact (cortical) bone, which forms a shell around the more porous, cancellous (trabecular) bone, or spongiosa. In the cancellous regions of the long bones, such as the proximal tibia shown here, the primary spongiosa is separated from the secondary spongiosa by an arbitrary boundary. Primary spongiosa is composed of primary bone, often laid down during growth on a calcified cartilage core that is subsequently remodeled. Secondary spongiosa is remodeled, reflects patterns of stress, and directs these stresses to the cortical shell.

Fig. 6.2 These photomicrographs show the three general microscopic types of bone, defined morphologically. Woven bone is composed of disorganized, randomly oriented collagen fibers. It is found at sites of fracture or inflammation. Lamellar bone can be divided into primary and secondary. Primary bone is deposited in layers by direct apposition on a substrate. It is found circling the endocortical and periosteal circumferences of a long bone, and within trabeculae. Secondary bone is formed by replacement of primary bone through the process of resorption and subsequent new bone formation. (Woven bone: polarized light. Primary lamellar bone: *left*, basic fuchsin; *right*, polarized light. Secondary osteonal bone: *Left*, toluidine blue; *right*, scanning electron microscopic image.)

the reason that it is difficult to reverse osteoporotic changes once trabecular connectivity has been lost. Primary lamellar bone also forms in rings around the endocortical and periosteal surfaces of whole bone (circumferential lamellae). Primary lamellar bone itself is not very vascular and can become very dense. Primary bone can also be arranged in concentric rings around a central canal—much like a secondary haversian system, except without a definable cement line. These primary osteons tend to be small with few concentric lamellae. In reality, primary osteons are modified vascular channels that have “filled in” by the addition of lamellae to the surface of the vascular space.

Secondary bone is the product of the resorption of preexisting bone and its replacement with new bone. This can occur within dense cortical bone (resulting in a secondary osteon, or haversian system) or begin on the surfaces of trabeculae (sometimes called a *hemi-osteon*). The distinction between primary and secondary bone is important because it is likely that control of primary bone apposition is different from replacement of preexisting bone by secondary bone. A secondary haversian system has a central vascular canal 50 to 90 μm in diameter. The blood vessels in the canal have the characteristics of capillaries and are generally paired within the canal. Venous sinusoids and lymphatic vessels are not found in haversian canals,

although it has been suggested that prelymphatic vessels may exist.¹ The vessel walls contain no smooth muscle but are fenestrated capillaries lined by an incomplete layer of endothelial cells, similar to vessels in other blood-forming organs like the spleen and bone marrow.² The vessel is accompanied about 60% of the time by two to seven unmyelinated or poorly myelinated nerve fibers.³ Because the capillaries have no smooth muscle, these nerves do not serve a vasomotor function but are primary sensory nerves or autonomic nerves from the sympathetic nervous system. Both primary afferents and sympathetic nerve fibers express neuropeptides that may play some role in regulating bone remodeling. Afferent nerve fibers also express GAP43, which is associated with axonal growth, and may reflect the need for vessel growth and reinnervation during bone remodeling.

Lining cells (resting osteoblasts) cover the haversian canal, which is surrounded by a series of concentric lamellae containing bone cells—osteocytes. The relationship between the size of the osteon and the size of its canal is a measure of the balance between bone resorption (osteon diameter) and bone formation (canal diameter). The secondary osteon is bounded by a cement line, probably composed largely of sulfated glycosaminoglycans.⁴ The cement line forms an effective boundary that can arrest cracks in bone and stop them from growing to a critical size.

COMPOSITION OF BONE

Bone is composed of organic and mineralized components, mainly consisting of a matrix of cross-linked type I collagen mineralized with nanocrystalline, carbonated apatite. Bone matrix incorporates a small fraction of noncollagenous proteins that serve to control collagen assembly and size as well as the process of mineralization and cell attachment. The mineral comprises about 65% to 67% of the bone by weight, the organic component about 22% to 25%, and water the remaining fraction (approximately 10%). Within the organic fraction, collagen makes up about 90%, with the remainder accounted for by several minor collagens (types III and V) and a variety of noncollagenous proteins, most of them extracellular, with cell protein accounting for about 15% of the noncollagenous proteins in bone.

Type I collagen in bone is formed by a triple helix composed of two $\alpha 1$ chains and a single $\alpha 2$ chain. At either end of the collagen molecule are an N-telopeptide and a C-telopeptide, which can be cleaved when bone is resorbed and which are used to measure bone resorption biochemically. These individual triple helical collagen molecules self-associate into a periodic arrangement of parallel molecules spaced in quarter-staggered array at distances of 67 nm between their ends to form collagen fibrils (Fig. e6.1). The spaces between the ends of the collagen molecules are known as *hole zones*, and the 35-nm gap zones that run longitudinally parallel between the molecules are known as *pores*. Poorly crystalline hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] nucleates within these spaces. The initial deposition of mineral—or primary mineralization—occurs rapidly after new bone is deposited, with about two thirds of the eventual mineral content achieved within about 3 weeks.⁵ As the bone tissue matures, the mineral crystals grow, become more platelike, and orient themselves parallel to one another and to the collagen fibrils. This process of crystal growth is sometimes called *secondary mineralization* and occurs over the next year or so until full mineralization is achieved. In cancellous bone, the c-axis or long axis of the mineral crystal aligns with the longitudinal axis of the trabeculae, whereas in cortical bone the mineral orients to the long axis of the osteon. Other elements can easily substitute into the hydroxyapatite crystal, changing its character and its ability to withstand mechanical loads. Collagen fibers can become cross-linked through the action of enzymes, which results in either immature or reducible (divalent) cross-links or mature and irreducible (trivalent) cross-links such as pyridinoline and deoxypyridinoline, which are formed from divalent forms through the action of lysyl oxidase. Divalent cross-links are rapidly converted into mature trivalent cross-links under normal circumstances, and so the quantity of divalent cross-links in bone is an indirect measure of remodeling rate. Divalent and trivalent cross-links are associated with the N- and C-terminals of the collagen molecule. Cross-links can also be formed between the fibers without the action of enzymes. These cross-links are formed by the condensation of arginine, lysine, and free sugars, or through various oxidation reactions, which results in the formation of advanced glycation end products. Accumulation of advanced glycation end products occurs in diabetes, making the bone more brittle and increasing the risk of fracture.

The skeletal noncollagenous proteins comprise 10% to 15% of total bone protein. These molecules constitute a wide range of polypeptide species and have roles in multiple skeletal processes in addition to functioning as structural scaffolding within the bone matrix.

Proteoglycans

Proteoglycans (PGs) are a ubiquitous family of molecules composed of a core protein and one or several covalently attached sulfated glycosaminoglycan chains. The glycosaminoglycans are linear polymers of repeated disaccharide units of hexosamine and hexuronic acid, except for keratan sulfate, in which hexuronic acid is replaced by galactose. The core proteins attached to the glycosaminoglycans are a diverse protein group and range in size from 10 to 500 kDa. The wide variety of protein structure may aid in directing the unique functional roles of each PG family.

The bone matrix contains PG families of several primary structures, including the following:

1. *Hyaluronan/CD44, chondroitin sulfate-containing* PGs are expressed in several regions of bone. Hyaluronan is expressed in focal regions within periosteum and endosteum, and surrounding most of the major bone cell types including osteoblasts, osteoprogenitor cells, osteoclasts, and osteocyte lacunae. CD44 is a cell-surface hyaluronan receptor that may play roles in guiding bone development and has been localized to osteoclasts, osteocytes, and bone marrow cells.⁶ Versican, a chondroitin sulfate-containing PG, may be enriched

during early osteoid formation and may provide a temporary framework in newly formed cartilage matrix during bone development.⁷ Results from studies of a mouse model carrying a disrupted versican gene (the hdf transgenic mouse) also suggest that mature versican PG may be essential for precartilaginous aggregation.⁸

2. *Heparan sulfate PGs (HSPGs)* are produced by osteoblast and osteoclast lineage cells. These molecules play important roles in cell-cell interactions during bone formation by trapping autocrine and paracrine heparin-binding fibroblast growth factor (FGF) family members, as well as acting as coreceptors with the FGF receptors. Also, other secreted molecules bind HSPGs, such as transforming growth factor- β (TGF- β , betaglycan) and osteoprotegerin (syndecans). The bioactivity of these factors is modulated by HSPGs, potentially through focusing of concentrations of these potent molecules near differentiating cells.
3. *Small leucine-rich PGs* are the most abundant of the PGs in bone matrix and include decorin, biglycan, fibromodulin, lumican, and osteoadherin. These molecules help to provide the structural organization of the bone matrix and interact with specific growth factors and collagen to increase factor concentration and bioactivity in the matrix (Fig. 6.3). The localization of these proteins in mature bone varies; decorin may localize with specific matrix areas, whereas biglycan is evenly distributed throughout the matrix. Decorin-null animals have alterations in collagen fibril size and bone shape,⁹ whereas biglycan-null animals demonstrate reduced bone mass due to lower osteoblast numbers and also show reduced numbers of osteoclasts.¹⁰ Small leucine-rich PGs play an essential role in the regulation of growth factor activity. In this regard, decorin, biglycan, and fibromodulin all possess the ability to bind to TGF- β ; however, decorin is the best-characterized of these proteins for the ability to bind this factor. Decorin enhances TGF- β binding with its cognate receptors and enhances its bioactivity, and, in concert, may act to sequester TGF- β in the collagen fibrils, thus reducing its activity. TGF- β activity is associated with increased apoptosis of osteoprogenitors; therefore biglycan and decorin appear to be essential for maintaining mature osteoblast numbers through regulation of the proliferation and survival of bone marrow progenitor cells.

Osteocalcin

Osteocalcin (OC) is a polypeptide posttranslationally modified to carry dicarboxylic glutamyl (Gla) residues, which relies on vitamin K for proper production (another identifier for OC is bone γ -carboxyglutamic acid [Gla] protein [BGLAP or BGP]). In humans, vitamin K is primarily a cofactor in the enzymatic reaction that converts glutamate residues into γ -carboxyglutamate residues in these vitamin K-dependent proteins including OC but also in proteins involved in blood clotting such as factor IX. These Gla-containing motifs are thought to enhance calcium binding, which may function to control mineral deposition and bone remodeling. A nine-residue domain proximal to the N-terminal of secreted OC shares high homology with the corresponding regions in known propeptides of the γ -carboxyglutamic acid-containing blood coagulation factors. This common structural feature may be involved in the posttranslational targeting of these proteins for γ -carboxylation.

OC may also act as a hormone to regulate the activity of osteoclasts and their precursors. In support of this, the skeleton of the OC-null animal manifests osteopetrosis compared with wild-type litter mates. In humans, OC is expressed largely by osteoblasts and osteocytes, and the measurement of this protein in serum has been used as a marker of bone turnover. OC messenger RNA (mRNA) is upregulated by vitamin D through interactions with *trans*-acting factors in vitamin D response elements in the OC promoter.¹¹ Due to its cell-specific expression, the OC promoter has proven to be invaluable as an active, functional DNA to drive foreign complementary DNAs in osteoblasts in transgenic animals.

Osteopontin

Osteopontin (OPN), also referred to as *secreted phosphoprotein-1*, is a member of the SIBLING (small integrin-binding ligand N-linked glycoprotein) family, which is a group of noncollagenous extracellular matrix proteins involved in bone mineralization. The genes coding for these proteins are localized to human chromosome band 4q21-25, have similar exon arrangements, and also include those coding for dentin matrix protein-1, dentin sialoprotein, dentin phosphoprotein, integrin-binding sialoprotein, and matrix extracellular phosphoglycoprotein (MEPE). The SIBLING proteins share common structural features, such as multiple phosphorylation sites, a highly acidic nature, the presence of an arginine-glycine-aspartic

Fig. e6.1 In the collagen fibril, molecules are organized in a quarter-staggered array, with hole and pore zones between them where mineral can deposit. The hole zones give the collagen fibril its banded appearance when viewed by electron microscopy. Cross-links are formed either through the action of enzymes (divalent and trivalent cross-links) or through nonenzymatic processes, the latter forming advanced glycation end products that can make bone behave in brittle fashion.

Fig. 6.3 Proteoglycans (PGs) regulate growth factors at several levels in the bone matrix and in bone cells. These polypeptides trap and locally concentrate endocrine and paracrine growth factors within the matrix. Soluble PGs such as decorin, biglycan, and perlecan also modulate activity through binding, thus controlling the concentrations of bioavailable factor. Membrane-bound PGs such as betaglycan and syndecan modulate ligand-receptor interactions and thus play roles in regulating intracellular signaling. FGF, fibroblast growth factor; FGFR, fibroblast growth factor receptor; OPG, osteoprotegerin; RANK, receptor activator of nuclear factor- κ B; RANKL, receptor activator of nuclear factor- κ B ligand; TGF- β , transforming growth factor- β ; TGF- β RI/RII, transforming growth factor- β receptor types I and II. (Adapted from Lamoureaux F, Baud'huin M, Duplomb L, et al. Proteoglycans: key partners in bone cell biology. *Bioessays* 2007;29:758-771.)

acid cell attachment domain, and proteolysis-resistant acidic serine aspartate-rich MEPE-associated motif.

OPN has a high sialic acid content and is produced by osteoblasts under stimulation by calcitriol. OPN is expressed within cement lines and may thus act as a promoter of adhesion and allow the arrangement of dissimilar tissues together in biologic composites such as teeth and bone.¹² OPN binds tightly to hydroxyapatite and may be involved in the anchoring of osteoclasts to the mineral of bone matrix. The vitronectin receptor, which has specificity for OPN, is focused within the osteoclast plasma membrane in the regions involved in the binding process. Long bones from OPN-null mice are indistinguishable from those from wild-type litter mates by radiography, but the relative amount of mineral in the more mature areas of the bone (central cortical bone) of the OPN-null mice is significantly increased, as is the mineral maturity (mineral crystal size and perfection) throughout all regions of the bone.¹³ *In vitro*, exogenous OPN inhibits inorganic pyrophosphate (PP_i)-dependent mineralization of a cultured osteoblast cell line.¹⁴ These findings indicate that OPN is a potent inhibitor of mineral formation as well as crystal growth and proliferation.

Osteonectin

Osteonectin, also referred to as *secreted protein acidic and rich in cysteine*, or SPARC, is a phosphoprotein that is the most abundant noncollagenous polypeptide expressed in bone. The mature protein binds selectively to hydroxyapatite, collagen fibrils, and vitronectin at distinct sites and may allow proper organization of the bone matrix through contacts with the cellular surface. Osteonectin also inhibits cellular proliferation through arrest of cells in the G1 phase of the cell cycle. It may regulate the activity of platelet-derived growth factor, vascular endothelial growth factor, and FGF-2. The osteonectin crystal structure has revealed a novel follistatin-like component and an extracellular calcium-binding region containing two EF-hand motifs. The osteonectin-null mouse develops severe osteopenia, which indicates that this gene may have roles in osteoblast proliferation and in mineralization.

Alkaline phosphatases and ectonucleotide pyrophosphatase/phosphodiesterases

Alkaline phosphatases are widely distributed and are membrane-bound glycoproteins that hydrolyze monophosphate esters.¹⁵ The liver-bone-kidney alkaline phosphatase, referred to as *tissue-nonspecific alkaline phosphatase* (encoded by the *ALPL* gene), acts as a lipid-anchored phosphoethanolamine and pyridoxal 5'-phosphate ectophosphatase. Loss-of-function mutations in the *ALPL* gene lead to hypophosphatasia, which is characterized by marked

defects in bone mineralization and is lethal in the infantile form. The PP_i produced by cells inhibits mineralization by binding to crystals, and the presence of PP_i may thus prevent the soft tissues from undergoing mineralization. The degradation of PP_i to inorganic phosphate by ALPL in bones and teeth may facilitate crystal growth; therefore it is thought that loss of function of the *ALPL* gene in hypophosphatasia results in accumulation of PP_i and reduced skeletal mineralization. Ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) is a type II transmembrane glycoprotein and a member of the ENPP family. ENPP1 has broad specificity and cleaves phosphodiester bonds of nucleotides and nucleotide sugars as well as pyrophosphate bonds of nucleotides and nucleotide sugars. This protein may function to hydrolyze nucleoside 5'-triphosphates to their corresponding monophosphates and may also hydrolyze diadenosine polyphosphates. Loss-of-function mutations in ENPP1 result in autosomal recessive hypophosphatemic rickets type 2, characterized by a rickets phenotype and elevation of FGF-23¹⁶ (see below).

Thrombospondin 1 and 2

The thrombospondins (TSPs) are a family of secreted glycoproteins of high molecular mass. TSP1 and TSP2 share high homology and form 450-kDa homotrimers. Both TSP1 and TSP2 are expressed by mesenchymal cells and chondrocytes during cartilage formation. As osteoblasts replace the mineralizing cartilage, TSP2 expression decreases in chondrocytes and increases in the matrix within areas undergoing ossification. TSP1 and TSP2 are strong angiogenic factors and therefore may also play a role in controlling blood vessel organization in forming bone.

In the developing animal, TSP1 and TSP2 are expressed in temporal and spatial patterns distinct for each gene. TSP1 (mouse gene, *Thbs1*) and TSP2 (*Thbs2*) have both been disrupted in mice and have unique phenotypes associated with each gene. *Thbs1* is a regulator of TGF- β *in vivo*, and these null animals have lower viability and prolonged wound healing. For skeletal phenotypes, this model has spine curvature and craniofacial alterations. *Thbs2* mice have increased cortical bone density, higher numbers of mesenchymal stem cells, and a resistance to bone loss due to ovariectomy. The fact that the *Thbs2*-null mice demonstrate less bone resorption than wild-type controls following ovariectomy may suggest a role for this molecule in estrogen-dependent reductions in bone mass and in the control of osteoclast function.

Proteins involved in mineralization Fibroblast growth factor 23

Fibroblast growth factor 23 (FGF-23) is a phosphaturic hormone produced in bone (Fig. 6.4), and the encoding gene was identified as the mutated gene

Fig. 6.4 Bone matrix mineralization involves an interplay of factors and is controlled by the balance between inorganic phosphate (P_i) and inorganic pyrophosphate (PP_i) and the expression of key local and systemic factors. An excess in P_i induces mineralization, whereas PP_i inhibits it. Proteins expressed in osteocytes and osteoblasts regulate mineralization. Specifically, PHEX and dentin matrix protein-1 (DMP1) induce mineralization, whereas fibroblast growth factor 23 (FGF-23) inhibits mineralization. Inhibition of mineralization by FGF-23 is believed to be due to inhibition of P_i reabsorption in the kidney, which would reduce blood and bone P_i levels. Induction of mineralization by PHEX and DMP1 may be secondary to inhibition of FGF-23 and thus increases in circulating P_i . The P_i levels in the extracellular matrix depend on dietary intake and on its rate of synthesis from PP_i catalyzed by alkaline phosphatase (AP). Conversely, the levels of PP_i depend on its conversion from P_i by ectonucleotide pyrophosphatase/phosphodiesterase enzymes (ENPP). Other bone-derived proteins such as matrix extracellular phosphoglycoprotein (MEPE), osteopontin (OPN), osteocalcin (OC), and osteonectin coordinately regulate mineralization, likely through direct interactions with the mineralized matrix. (Adapted from Bellido T, Plotkin LJ, Bruzzaniti A. Bone cells. In: Burr DB, Allen MR, editors. *Basic and applied bone biology*. San Diego: Academic Press; 2014, p. 27-46, Figure 14.)

in autosomal dominant hypophosphatemic rickets (ADHR), a metabolic bone disorder of isolated renal phosphate wasting.¹⁷ Full-length FGF-23 (32 kDa) is the biologically active form of the protein and is inactivated upon cleavage into 20- and 12-kDa protein fragments. Intracellular cleavage of FGF-23 occurs at a subtilisin-like proprotein convertase site (R₁₇₆XXR₁₇₉/S), which inactivates the protein. The human FGF-23 ADHR mutations R176Q, R179Q, and R179W destroy this site and stabilize the full-length active form of the protein. FGF-23 acts in the kidney to inhibit phosphate reabsorption by reducing expression of the proximal tubule type I sodium-phosphate cotransporters Npt2a¹⁸ and Npt2c. The subsequent low serum phosphate level results in marked osteomalacia and rickets, fracture, and dental anomalies. Application of *in-situ* hybridization to adult trabecular bone revealed the presence of FGF-23 mRNA in osteocytes and flattened bone-lining cells. In regions of active bone formation, newly formed osteocytes and osteoprogenitor cells also express FGF-23.¹⁹ FGF-23 levels are elevated *in vivo* by increased serum phosphate and 1,25-dihydroxyvitamin D concentrations, and FGF-23 then completes the feedback loop by reducing phosphate reabsorption and 1,25-dihydroxyvitamin D production in the kidney. Evidence also indicates that FGF-23 is directly regulated by parathyroid hormone (PTH) in osteocytes.²⁰

Whether FGF-23 has direct effects on the skeleton is uncertain, because the FGF-23 coreceptor α -Klotho is predominantly expressed in the kidney and parathyroid glands. However, because FGF-23 is produced in bone, FGF-23 expression and its actions on serum phosphate concentrations may be coordinated with intraskeletal signals to allow proper bone formation and mineralization.

PHEX

X-linked hypophosphatemia, a disorder of rickets and osteomalacia, is caused by inactivating mutations in *PHEX* (phosphate-regulating gene with homologies to endopeptidases on the X chromosome).²¹ *PHEX* encodes a protein that is similar to the M13 family of membrane-bound metalloproteases such as neutral endopeptidase and endothelin-converting enzymes 1 and 2 (see Fig. 6.4). These proteases are known to cleave small peptide hormones. Mutations in *PHEX* lead to dramatic over expression of FGF-23;

however, the *PHEX* substrate and molecular mechanisms underlying this increase are currently unknown.

Dentin matrix protein-1

Dentin matrix protein-1 (DMP1), like OPN, is a member of the SIBLING gene family. DMP1 is highly expressed in osteocytes and is comprised of 513 residues but is secreted in bone and dentin as 37-kDa N-terminal (residues 17 to 253) and 57-kDa C-terminal (residues 254 to 513) fragments from a 94-kDa full-length precursor (see Fig. 6.4). Recombinant DMP1 binds calcium-phosphate ions and the N-telopeptide region of type I collagen with high affinities, so *in vivo* DMP1 may regulate local mineralization processes in bone and teeth. The C-terminal portion of DMP1 has been implicated in DNA binding, in gene regulation, and as an integrin-binding protein. Inactivating mutations in DMP1 result in the metabolic bone disease autosomal recessive hypophosphatemic rickets, which is associated with elevated FGF-23 levels in these patients. As shown in the *Dmp1*-null mouse (and in the Hyp mouse model of X-linked hypophosphatemia), the primary cellular defect caused by loss of *Dmp1* may be an alteration in osteoblast to osteocyte maturation, leading to inappropriate expression of typically “osteoblastic” or “early osteocyte” genes such as type I collagen, alkaline phosphatase, and FGF-23 in mature embedded osteocytes. The relationship of DMP1 to cell differentiation is currently unknown. Interestingly, FAM20c, a novel secreted kinase,²² has been shown to phosphorylate the SIBLING proteins DMP1 and MEPE (see next section). Loss of FAM20c in mice results in a DMP1-null phenotype,²³ which indicates a complex relationship between the phosphorylation of extracellular matrix proteins and their normal functions.

Matrix extracellular phosphoglycoprotein

Another member of the SIBLING family found in the mineralizing matrix is matrix extracellular phosphoglycoprotein, or MEPE (see Fig. 6.4). MEPE is predominantly expressed in odontoblasts and osteocytes embedded in the mineralized matrix. *In-vitro* studies of human osteoblast cell cultures indicate that MEPE expression is the highest during the mineralization phase.²⁴ *Mepe*-null mice display increased trabecular and cortical bone mass, due to increases in both osteoblast number and activity, and these mice are also resistant to age-dependent trabecular bone loss.²⁵ Taken together, these findings indicate that MEPE likely has a role as an important gene for the negative regulation of skeletal mineralization.

Growth factors

Multiple growth factors, either produced within bone or circulating to bone, are critical for skeletal development and function. These factors may be sequestered within bone matrix via the bloodstream or may be produced by the major bone cell types and act as paracrine and autocrine factors.

Insulin-like growth factors

The insulin-like growth factors IGF-1 (somatomedin C) and IGF-2 (somatomedin A) are produced primarily in the liver but are also produced in bone. These factors predominantly circulate complexed with IGF binding proteins (IGFBPs) to facilitate their transport to tissues. IGFBPs can either enhance or inhibit IGF activity. IGF-1 and -2 act through the IGF-1 receptors (IGFR1 and IGFR2) and possess bioactivity that promotes cell proliferation and differentiation.

The IGF-1-null mouse has reduced cortical bone and femur length; however, trabecular density is increased. *In-vitro* findings suggest that IGF-1 also increases osteoclastogenesis, and IGF-1-null mice have reduced levels of receptor activator of nuclear factor- κ B ligand (RANKL) in osteoblasts isolated from bone marrow. Therefore IGF-1 may regulate osteoclastogenesis through direct and indirect actions. Overexpression of IGF-1 specifically in osteoblasts leads to increased bone mineral density and increased trabecular volume, although osteoblast numbers are not increased.²⁶ These studies suggest that IGF-1 acts directly on osteoblasts to enhance their function. Specific removal of IGFR1 from osteoblasts results in decreased trabecular number and volume and a dramatic decrease in bone mineralization, which further supports the role of the IGFs with regard to osteoblasts. Less is known regarding the functions of IGF-2 in bone. However, it has been suggested that IGF-2 may be a local regulator of bone cell metabolism.

Bone morphogenetic protein family

Bone morphogenetic proteins (BMPs) are members of the TGF- β superfamily. There are now more than 20 BMP-related proteins, which are classified into subgroups based on structure and function. These factors play important roles in skeletal development by directing the fate of mesenchymal cells, through differentiation of these precursor cells into cells of the osteoblastic

lineage, and by inhibiting their differentiation into myoblastic lineage cells. BMPs also increase osteoclastogenesis, which is tightly coordinated with osteoblastogenesis. BMPs activate specific receptors and induce cell signaling by phosphorylating cytoplasmic receptor-regulated Smads, which enter the nucleus to recruit transcription factors and enhance gene expression. The human disorder fibrodysplasia ossificans progressiva is a disease of dramatic ectopic bone formation, which can be accelerated following blunt trauma. A recurrent mutation in activin receptor 1A/activin-like kinase 2, a BMP type I receptor, was reported as the molecular cause of fibrodysplasia ossificans progressiva.²⁷ These findings underscore the potent effects of BMP signaling on bone formation.

Fibroblast growth factors

Members of the FGF family of proteins primarily act as paracrine and autocrine factors and bind to one or several of four FGF receptors (FGFRs). FGFRs normally exist as an inactivated monomer. With FGF binding in the presence of heparin/heparan sulfate, the FGFRs dimerize, which leads to the autophosphorylation of tyrosine residues. The FGF family has potent effects on bone development. This is clearly evident by the fact that activating mutations in FGFR1 and FGFR2 are responsible for disorders of cranio-synostosis and limb patterning, and FGFR1 and FGFR3 mutations result in disorders of hypochondroplasia and achondroplasia. The FGFs interact with HSPGs and are sequestered within the mineralizing matrix. In addition, the HSPG syndecan may stabilize FGF-FGFR interactions and promote FGF signaling and bioactivity.

The FGF family members play important roles in bone development and formation. Expression of several FGF ligands including FGF-2, FGF-5, FGF-6, FGF-7, and FGF-9 has been observed in mesenchyme surrounding initial condensation. In limb bud, FGFR1 and FGFR2 are expressed in condensing mesenchyme. In rat growth plates, mRNAs encoding all four FGFRs and FGF-2 can be detected, and FGF-2 is also present in osteoblasts. FGF-2 treatment of osteoblasts enhances the binding of Runx2 to the Cbfa1 consensus sequence in the OC promoter and may therefore have a role in differentiation.

Transforming growth factor- β

Transforming growth factor- β (TGF- β) controls proliferation, differentiation, and other functions in many cell types. TGF- β 1, TGF- β 2, and TGF- β 3 all function through the type I and type II TGF receptors. The type I TGF- β receptor forms a heterodimer with the type II TGF- β receptor. TGF- β stimulation leads to activation of SMAD2 and SMAD3, which form complexes with SMAD4 that accumulate in the nucleus and regulate the transcription of target genes.

TGF- β 1 is the most abundant growth factor in human bone; it is localized within the bone matrix and has functions both during embryonic development and in mature bone. During embryonic development, TGF- β 1 plays a role in cell migration, controlling epithelial-mesenchymal interactions, and the formation of cellular condensations, which influence bone shape. This factor also plays a key role in inducing mesenchymal cell differentiation to either chondrocytes or osteoblasts. In adult bone, TGF- β 1 controls osteoblast differentiation, which affects matrix formation and mineralization. TGF- β 1 inhibits the expression of the differentiation markers Runx2 and OC in osteoblast cell lines, and its functions interplay with those of other systems in bone such as the PTH and the Wnt/ β -catenin systems.

The skeletal disorder Camurati-Engelmann disease (CED) highlights the importance of TGF- β 1 in skeletal formation. CED is a progressive diaphyseal dysplasia characterized by hyperostosis and sclerosis of the diaphyses of the long bones. The *TGFB1* gene was screened and three different heterozygous missense mutations were found in exon 4 in the nine families examined. All of the mutations in the CED patients were located either at C225 or near R218, which suggests the importance of this region in activating TGF- β 1 in the bone matrix.

Platelet-derived growth factor and vascular endothelial growth factor

All platelet-derived growth factors (PDGFs) and vascular endothelial growth factors (VEGFs) are dimers of disulfide-linked polypeptide chains, encoded by nine different genes that direct production of four different PDGF chains (PDGF-A, PDGF-B, PDGF-C, and PDGF-D) and five different VEGF chains (VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor). All members of these families carry a growth factor core domain that is necessary for receptor activation. PDGFs mediate their bioactivity through two receptors, PDGFR- α and PDGFR- β . These receptors both have five extracellular immunoglobulin loops for ligand binding and an intracellular tyrosine kinase domain. The VEGFs act through a homologous family of receptors,

VEGFR1, VEGFR2, and VEGFR3. PDGFs act primarily as paracrine growth factors.

PDGF is chemotactic and mitogenic for osteoblasts and osteoprogenitor cells, and it upregulates cytokines that are crucial to bone healing. This factor also destabilizes blood vessels during healing to allow sprouting of new vessels. VEGF is produced by many cell types including fibroblasts, hypertrophic chondrocytes, and osteoblasts. VEGF may act not only in bone angiogenesis and vascular differentiation but also in aspects of development, such as chondrocyte and osteoblast differentiation, as well as osteoclast recruitment.

BONE CELLS

Bone development and the adaptation of the adult skeleton to mechanical needs and hormonal changes depend on the ability of bone cells to resorb and form bone in the right places and at the right time. Bone growth, modeling, and remodeling are defined by the spatial and temporal relationship between bone resorption and bone formation. Osteoclasts resorb bone, osteoblasts form bone, and osteocytes detect the need for bone augmentation or reduction and coordinate the activity of osteoclasts and osteoblasts.

Osteoclasts

Osteoclasts are the primary bone-resorptive cells. They are needed for bone modeling, which leads to changes in the shape of bones, and for bone remodeling, which maintains the integrity of the adult skeleton. Osteoclasts originate from precursors of the monocyte/macrophage family of the hematopoietic lineage that differentiate to multinucleated cells upon stimulation with RANKL and macrophage colony-stimulating factor (M-CSF) (Fig. 6.5). Upon completing bone resorption, all osteoclasts undergo programmed cell death or apoptosis and disappear from the bone surface.

Osteoclast morphology and function

Osteoclasts adhere firmly to bone through the interactions established between integrins expressed in the osteoclast membranes with collagen, fibronectin, and other bone matrix proteins. Expression of α_v and α_3 integrin is induced during osteoclast differentiation, and the integrin binds to the amino acid sequence Arg-Gly-Asp present in OPN and bone sialoprotein. The importance of these events for osteoclast activity is underscored by the inhibition of resorption with competitive Arg-Gly-Asp ligands²⁸ and a progressive increase in bone mass due to osteoclast dysfunction in mice null for β_3 integrin.

The intimate contact between the osteoclast and the bone matrix creates a space called the *sealing zone*. There is also polarization of the osteoclast fibrillar actin into a circular structure called the *actin ring*, containing podosomes composed of an actin core surrounded by $\alpha_v\beta_3$ integrins and associated cytoskeletal and signaling proteins. Thus the area in which the osteoclast apposes the bone is isolated from the general extracellular space and becomes acidified by the activity of a proton pump and a chloride channel.²⁸ The low pH in this area dissolves the mineral and exposes the organic matrix, which is subsequently degraded by the activity of lysosomal cathepsin K and matrix metalloproteases. These degrading enzymes are transported into acidified vesicles that fuse with the osteoclast plasmalemma forming a villous structure referred to as the *ruffled border*. This structure and the actin ring are essential features of a resorbing osteoclast, and abnormalities of either structure lead to arrested bone resorption.

The cytoplasmic domains of integrins serve as platforms for signaling proteins involved in osteoclast function, such as the kinase Src, which is crucial for osteoclast attachment and resorption. Src regulates podosome disassembly and ruffled membrane formation by its ability to interact with the focal adhesion-related kinase Pyk2 and the proto-oncogene c-Cbl. Rho, Rac, and the guanine nucleotide exchange factor Vav3, which activates guanosine diphosphatases into guanosine triphosphatases, also play a central role in modifying the resorptive capacity of osteoclasts by modulating the actin cytoskeleton. Osteoclast resorption products are transported in vesicles through the cytosol to the basolateral surface and discharged to the extracellular milieu or directly released to the surrounding fluid after osteoclast retraction from the resorption pits.

Osteoclast formation and differentiation

Mature, multinucleated osteoclasts are formed by fusion of mononuclear precursors of the monocyte/macrophage lineage (see Fig. 6.5). The earliest recognized osteoclast precursor is the granulocyte-macrophage colony-forming unit, which also gives rise to granulocytes and monocytes.

Fig. 6.5 Osteoclast differentiation is governed by receptor activator of nuclear factor- κ B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF) secreted by osteoblasts and osteocytes, which control various steps of the osteoclast differentiation process, including precursor proliferation, commitment, differentiation, and maturation. Osteoprotegerin (OPG), which is also secreted by osteoblasts and osteocytes, acts as a decoy receptor for RANKL and reduces osteoclast differentiation. (From Bellido T, Plotkin LJ, Bruzzaniti A. Bone cells. In: Burr DB, Allen MR, editors. *Basic and applied bone biology*. San Diego: Academic Press; 2014, p. 27-46, Figure 5.)

Osteoclast precursors proliferate in response to growth factors such as interleukin-3 (IL-3) and colony-stimulating factors like granulocyte-macrophage colony-stimulating factor (GM-CSF) and M-CSF to form postmitotic, committed mononucleated osteoclast precursors, which differentiate and fuse to form multinucleated osteoclasts under the influence of RANKL, a member of the tumor necrosis factor (TNF) family of ligands.

M-CSF and RANKL are critical for osteoclastogenesis, and deletion of M-CSF, RANKL, or RANK, the receptor for RANKL expressed by osteoclasts and their precursors, inhibits osteoclast differentiation, leading to osteopetrosis in mice. Both M-CSF and RANKL are expressed by bone marrow stromal cells and osteoblastic cells, as well as T lymphocytes. Importantly, osteocytes have now been found to be a major source of M-CSF and RANKL, as well as osteoprotegerin (OPG), the RANKL decoy receptor,^{29,30} which suggests a central role of these cells in osteoclastogenesis (see Fig. 6.5). M-CSF contributes to osteoclast differentiation, migration, and survival by binding to its receptor c-Fms on osteoclast precursors, whereas RANKL facilitates osteoclast formation via direct binding to the receptor RANK. RANKL is expressed on the cell surface and is also secreted as a soluble form. Although the soluble form of RANKL is found in the circulation and its presence is sufficient to induce differentiation of osteoclast precursors *in vitro*, its actual role in osteoclast formation *in vivo* remains unproven.

RANKL expression is upregulated by hormones and cytokines known to induce osteoclast generation. This explains the long-observed property of primary osteoblastic cells or osteoblastic cell lines that, upon treatment with vitamin D, PTH, or IL-11, IL-6, TNF, and IL-1, support osteoclast development when co-cultured with osteoclast precursors derived from spleen or bone marrow. RANKL mediates several aspects of osteoclast differentiation, including fusion of mononucleated precursors into multinucleated cells, acquisition of osteoclast-specific markers, attachment of osteoclasts to the bone surfaces, stimulation of resorption, and promotion of osteoclast survival. Although M-CSF contributes to RANKL effects, RANKL appears to play a dominant role in bone resorption. Thus, whereas M-CSF-null mice recover with time from the decreased osteoclast number and activity, RANKL knockout mice do not. Furthermore, RANKL appears to stimulate osteoclast formation and resorption in mice even in the absence of functional M-CSF.³¹

RANKL activates several signal transduction pathways involving the recruitment of the adapter protein TRAF6 (TNF receptor-associated factor 6) to the intracellular domain of the receptor RANK. TRAF6 in turn activates kinase-dependent signaling as well as transcription factors. Among them, NF- κ B has been shown to undergo nuclear translocation leading to upregulation of c-Fos. Fos, in turn, binds to nuclear factor of activated T cells, cytoplasmic 1 (NFATc1) and upregulates genes crucial for osteoclast differentiation and function. Although other signaling pathways are activated by RANKL in osteoclasts, the evidence that deletion of NF- κ B, c-fos/AP1, and NFATc1 leads to osteoclast dysfunction demonstrates the crucial role of these genes in osteoclasts.³¹

OPG is an inhibitor of RANK activation and osteoclastogenesis that also belongs to the TNF family of receptors. OPG is a secreted protein with no transmembrane domain, and therefore it has no direct signaling capabilities. OPG suppresses osteoclast formation and resorption by binding to RANKL, thereby impeding RANKL interaction with RANK.

Osteoclast apoptosis

All osteoclasts undergo apoptosis and disappear from the bone surface after completing bone resorption. High concentrations of extracellular calcium, like the ones present in resorption cavities, induce osteoclast apoptosis *in vitro* and may be the triggering event. Fas ligand stimulates osteoclast apoptosis, and Fas-deficient mice exhibit more osteoclasts and decreased bone mass, which suggests that this pathway controls osteoclast life span *in vivo*. Osteoclast apoptosis might also result from loss of survival signals provided by integrin interactions with the matrix or by changes in the production of cytokines or growth factors that preserve osteoclast viability. Potential antiapoptotic factors are M-CSF and RANKL, the same cytokines that induce osteoclast differentiation. TNF- α and IL-1 also delay osteoclast apoptosis. All these cytokines activate the extracellular signal-regulated kinases (ERKs), which is required for osteoclast survival. Phosphatidylinositol 3'-kinase (PI3-K) and its target the kinase Akt are required for osteoclast differentiation but not for survival. Instead, mammalian target of rapamycin (mTOR), another PI3-K target, is required for the antiapoptotic actions of M-CSF, RANKL, and TNF- α in osteoclasts. Since mTOR is also activated by ERKs, it appears to be a point of convergence in the action of prosurvival kinases in osteoclasts.

RANKL, TNF- α , and IL-1 also activate NF- κ B, a transcription factor shown to inhibit apoptosis in various cell types. Downregulation of NF- κ B mRNA inhibits IL-1-dependent survival, and blockade of NF- κ B binding to DNA with specific oligonucleotides induces apoptosis. However, osteoclast precursors lacking NF- κ B subunits have normal survival rates, and inhibition of NF- κ B activation via a dominant-negative IKK2 does not affect the ability of IL-1 to promote osteoclast survival. Therefore the relevance of NF- κ B signaling for osteoclast survival is still controversial.

Regulation of osteoclast generation and survival

In the bone-remodeling unit, the rate of osteoclast generation determines the extension of the bone-remodeling unit, whereas the life span of osteoclasts determines the depth of resorption. Although both genesis and apoptosis of osteoclasts lead to changes in osteoclast number and bone resorption, alteration of osteoclast life span might represent a more effective mechanism to accomplish rapid changes in bone resorption rate.

Sex steroids have profound effects on osteoclasts. Both estrogens and androgens inhibit osteoclast generation by regulating the production of pro-osteoclastogenic cytokines (such as IL-6 and IL-1) by cells of the stromal/osteoblastic lineage. Estrogens also induce apoptosis of mature osteoclasts. This, together with an inhibitory effect of the hormones

Fig. 6.6 Osteoblastogenesis is controlled by transcription factors that affect the proliferation and differentiation of osteoblast precursors. Mature osteoblasts can surround themselves by bone matrix and differentiate further to become osteocytes, flatten to cover the quiescent bone surface as lining cells, or die by apoptosis. (From Bellido T, Plotkin LI, Bruzzaniti A. *Bone cells*. In: Burr DB, Allen MR, editors. *Basic and applied bone biology*. San Diego: Academic Press; 2014, p. 27-46, Figure 7.)

on osteoblast generation, leads to attenuation of the rate of bone remodeling.

Mice receiving excess glucocorticoids exhibit reduced osteoclast progenitors, but cancellous osteoclast number does not decrease in the early phases of the disease, because glucocorticoids prolong the life span of preexisting osteoclasts. This effect may account for the early transient increase in bone resorption in patients with hyperglucocorticoidism. In contrast to the rapid pro-survival effect of glucocorticoids on mature osteoclasts, glucocorticoids induce a decrease in osteoclast formation caused by a reduction in the pool of osteoblastic cells that support osteoclastogenesis. This effect leads to the typical low remodeling rate observed in chronic glucocorticoid-induced osteoporosis.

Osteoblasts

Osteoblasts are the cells responsible for bone formation. They originate from mesenchymal progenitors, which also give rise to chondrocytes, muscle cells, and adipocytes (Fig. 6.6). Commitment of mesenchymal cells to the osteoblastic lineage depends on the specific activation of transcription factors induced by morphogenetic and developmental proteins that carry out the functions of bone matrix protein secretion and bone mineralization. Upon completion of bone matrix formation, some mature osteoblasts remain entrapped in bone as osteocytes, some flatten to cover quiescent bone surfaces as bone-lining cells, and most die by apoptosis.

Osteoblast function

The main function of osteoblasts is to synthesize collagen type I and other specialized matrix proteins that serve as a template for the subsequent mineral deposition in the form of hydroxyapatite. Mature osteoblasts actively engaged in this process are recognized by their location on the bone surface and by their morphologic features typical of cells secreting high levels of proteins: cuboidal shape with large nucleus, enlarged Golgi apparatus, and extensive endoplasmic reticulum. Osteoblasts express high levels of alkaline phosphatase and OC, and the level of these proteins in blood reflects the rate of bone formation.

Interaction of osteoblasts among themselves, with lining cells, and with bone marrow cells is established by adhesion junctions, tight junctions, and gap junctions. Adhesion junctions mainly mediated by cadherins and tight junctions serve to join cells and facilitate their anchorage to the extracellular matrix. Changes in the expression level of the major cadherins expressed in osteoblasts, N-cadherin and cadherin 11, influence osteoblast differentiation and survival. Intercellular communication among osteoblasts and neighboring cells is maintained by cell coupling via gap junctions. Opening of gap junction channels contributes to coupling and the coordination of responses within a cell population. The major gap junction protein expressed in bone cells is connexin 43. Its absence or dysfunction leads to impaired osteoblast differentiation, premature apoptosis of osteoblasts and osteocytes, and deficient response to hormones and pharmacotherapeutic agents.³² Furthermore, gap junction communication is fundamental for the maintenance of a continuum from bone, where osteocytes reside, through bone surface

cells, osteoblasts and osteoclasts, bone marrow cells, and endothelial cells of the blood vessels.³³ This functional syncytium might be responsible for the coordinated response of the bone tissue to changes in physical and chemical stimuli, as it will be discussed later. Interactions between osteoblasts and the bone matrix via integrins also modulate osteoblast differentiation, function, and survival. In particular, loss of antiapoptotic signals provided by the extracellular matrix causes apoptosis, a phenomenon referred to as *anoikis*.

Osteoblast formation and differentiation

The process of osteoblastogenesis can be divided into steps comprising proliferation, extracellular matrix development and maturation, mineralization, and apoptosis. Each stage is characterized by activation of specific transcription factors and genes leading to a succession of osteoblast phenotypic markers (see Fig. 6.6). Transcription factors of the helix-loop-helix family (Id, Twist, and Dermo) are expressed in proliferating osteoblast progenitors and are responsible for maintaining the osteoprogenitor population by inhibiting the expression of genes that characterize the osteoblast mature phenotype. Transcription factors of the activating protein family such as c-fos, c-jun, and junD, are expressed during proliferation as well as later in the differentiation pathway and may activate or repress transcription. Runx2 and osterix are essential for establishing the osteoblast phenotype. Their absence from the mouse genome results in lack of skeletal mineralization and perinatal lethality. Runx2 and osterix regulate the expression of other genes that control bone formation and remodeling including OC and RANKL. Runx2 regulates differentiation, survival, and function of osteoblasts by affecting several signaling pathways, including those activated by Wnts, BMPs, integrins, and the PTH receptor.

Osteoblast apoptosis

Upon completing the process of bone formation, 60% to 70% of osteoblasts die by apoptosis; the remainder becomes lining cells or osteocytes. Apoptosis occurs throughout all stages of osteoblast life.³⁴ The prevalence of osteoblast apoptosis in bone sections can be quantified by measuring fragmented DNA. Apoptosis of cultured osteoblasts has been extensively studied using several methods,³⁵ including increased activity of initiator or effector caspases, presence of cleaved genomic DNA by TUNEL or ISEL assay, and nuclear fragmentation and chromatin condensation using fluorescent dyes that bind to DNA. Examination of the nuclear morphology of cells transfected with fluorescent proteins containing a nuclear localization sequence has proven a particularly useful tool for studying apoptosis in cells cotransfected with genes of interest. Cell detachment from the substrate, changes in the composition of the plasma membrane, and changes revealing cell shrinkage are also features that have been used to detect and quantify apoptotic cells.

Regulation of osteoblast generation and apoptosis

Most major regulators of skeletal homeostasis influence both generation and survival of osteoblasts. The BMP and Wnt signaling pathways promote osteoblast differentiation, but whereas BMPs induce osteoblast apoptosis,

Wnts inhibit it. BMPs induce apoptosis of mature osteoblasts as well as of mesenchymal osteoblast progenitors in interdigital tissues during the development of the hands and feet. Wnt signaling has a profound effect on bone as shown by the high-bone-mass phenotype of mice and humans with activating mutations of low-density lipoprotein receptor–related protein 5 (LRP5), which together with Frizzled proteins are receptors for Wnt ligands. Wnts stimulate differentiation of undifferentiated mesenchymal cells toward the osteoblastic lineage and stimulate differentiation of pre-osteoblasts. Canonical Wnt signaling in osteoblasts also affects osteoclasts by enhancing the expression of the RANKL decoy receptor OPG, which leads to inhibition of osteoclast development. In addition, Wnt signaling inhibits apoptosis of mature osteoblasts and osteocytes.³⁶ The increased bone formation exhibited by mice lacking the Wnt antagonist known as *secreted frizzled related protein-1* (sFRP-1) is associated with decreased osteoblast and osteocyte apoptosis. The prevalence of osteoblast and osteocyte apoptosis is also decreased in mice expressing the high bone mass–activating mutation of LRP5 (G171V), which exhibit reduced ability to bind the Wnt antagonist sclerostin secreted by osteocytes. Consistent with this, sclerostin induces osteoblast apoptosis *in vitro*. Moreover, reduction of sclerostin levels by PTH and mechanical loading increases osteoblast number and activity as a result of stimulation of osteoblast differentiation and increased survival.^{37,38} Activation of Wnt signaling *in vitro* by ligands known to activate the so-called canonical as well as noncanonical pathways also prevents apoptosis of osteoblast progenitors and differentiated osteoblasts through a mechanism that involves the Src/ERK and PI3/AKT pro-survival kinases.³⁹

Glucocorticoids induce rapid bone loss resulting from a transient increase in resorption due to delayed osteoclast apoptosis. This initial phase is followed by a sustained and profound reduction in bone formation and turnover due to decreased osteoblast and osteoclast generation and increased osteoblast apoptosis.

Both persistent excess of PTH, as in hyperparathyroidism, and intermittent elevation of PTH (by daily injections) increase the number of osteoblasts. Sustained PTH elevation inhibits the expression of sclerostin, with a consequent increase in Wnt signaling and in differentiation of osteoblast precursors. A major effect of intermittent elevation of PTH is inhibition of apoptosis of osteoblasts, which thereby prolongs their life span and ability to form bone.

Osteocytes

Osteocytes are former osteoblasts that become entombed during the process of bone deposition and are regularly distributed throughout the mineralized bone matrix. Osteocyte bodies are individually encased in lacunae and exhibit cytoplasmic dendritic processes that run along narrow canaliculi excavated in the mineralized matrix. Osteocytes communicate with each other, with cells on the bone surface, and with cells of the bone marrow through gap junctions established between cytoplasmic processes of neighboring cells. Today it is accepted that osteocytes are the mechanosensory cells. Osteoblasts and osteoclasts are present on bone only transiently, in low number, and in variable locations. On the other hand, osteocytes are the most abundant resident cells and are present in the entire bone volume. Osteocytes are also the core of a functional syncytium that extends from the mineralized bone matrix to the bone surface and the bone marrow, and all the way to the blood vessels. This strategic location permits the detection of variations in mechanical signals as well as in levels of circulating factors, and allows amplification of the signals leading to adaptive responses.

Osteocyte apoptosis: consequences and regulation

Osteocytes are long-lived cells. However, like osteoblasts and osteoclasts, osteocytes die by apoptosis, and decreased osteocyte viability accompanies the bone fragility syndromes that characterize glucocorticoid excess, estrogen withdrawal, and mechanical disuse.³⁴ Conversely, preservation of osteocyte viability might explain at least part of the antifracture effects of bisphosphonates, which cannot be completely accounted for by changes in bone mineral density.⁴⁰

Preservation of osteocyte viability by mechanical stimuli

Osteocytes interact with the extracellular matrix in the pericellular space through discrete sites in their membranes, which are enriched in integrins and vinculin, as well as through transverse elements that tether osteocytes to the canalicular wall. Loading of the bones induces extracellular matrix deformation and fluid flow through the canaliculi, producing tension in the tethering elements and strain on osteocyte membranes. The consequent integrin engagement leads to intracellular signaling. Physiologic levels of

mechanical strain imparted by stretching or pulsatile fluid flow prevent apoptosis of cultured osteocytes. Mechanotransduction is accomplished by molecular complexes assembled at caveolin-rich domains of the plasma membrane and composed of integrins, cytoskeletal proteins, and kinases, including the focal adhesion kinase FAK and Src, which results in activation of the ERK pathway and osteocyte survival. Intriguingly, a ligand-independent function of the estrogen receptor is indispensable for mechanically induced ERK activation in both osteoblasts and osteocytes. This observation is consistent with reports that mice lacking estrogen receptor- α and estrogen receptor- β exhibit a poor osteogenic response to loading.

In vivo mechanical forces also regulate osteocyte life span. Apoptotic osteocytes are found in unloaded bones or in bones exposed to high levels of mechanical strain. In both cases, increased osteocyte apoptosis is observed before any evidence of increased osteoclast resorption. Apoptotic osteocytes accumulate in areas subsequently removed by osteoclasts. Targeted ablation of osteocytes in transgenic mice is sufficient to induce osteoclast recruitment and resorption leading to bone loss. These findings led to the notion that dying osteocytes become the beacons for osteoclast recruitment to the vicinity and the resulting increase in bone resorption.⁴¹ Whether living osteocytes continually produce molecules that restrain osteoclast recruitment or whether in the process of undergoing apoptosis osteocytes produce pro-osteoclastogenic signals remains to be determined. Taken together with the evidence that osteocyte apoptosis is inhibited by estrogens and bisphosphonates,^{40,42} these findings raise the possibility that preservation of osteocyte viability contributes to the antiremodeling properties of these agents.

Osteocyte apoptosis and aging

One of the purported functions of the osteocyte network is to detect microdamage and trigger its repair. During aging, there is an accumulation of microdamage and a decline in osteocyte density accompanied by decreased prevalence of osteocyte-occupied lacunae, an index of premature osteocyte death. Age-related loss of osteocytes due to apoptosis could be partially responsible for the disparity between bone quantity and quality that occurs with aging. The decline in physical activity and thus reduced skeletal loading with old age is a potential mechanism for the increased prevalence of osteocyte (and osteoblast) apoptosis, as is the loss of estrogen in women during and after menopause.

Hormonal regulation of osteocyte life span

Estrogen and androgen deficiency both lead to increased prevalence of osteocyte apoptosis. Conversely, estrogens and androgens inhibit apoptosis of osteocytes as well as osteoblasts.⁴² This antiapoptotic effect is due to rapid activation of the Src/Shc/ERK signaling pathway through nongenotropic actions of the classical receptors for sex steroids. This effect requires only the ligand-binding domain of the receptor, and unlike the classical genotropic action of the receptor protein, it is eliminated by nuclear targeting.

Excess of glucocorticoid activity in bone may also contribute to induction of osteocyte (and osteoblast) apoptosis, because aged mice exhibit higher serum levels of corticosterone, elevated adrenal weight, and increased expression in bone of 11 β -hydroxysteroid dehydrogenase type 1 (11 β -HSD1), the enzyme that amplifies glucocorticoid action. The apoptotic effect of glucocorticoids is reproduced in cultured osteocytes and osteoblasts in a manner strictly dependent on the glucocorticoid receptor.³⁴ Induction of osteocyte and osteoblast apoptosis by glucocorticoids can result from the direct action of the steroids, because overexpression of the enzyme that inactivates glucocorticoids, 11 β -HSD2, specifically in these cells abolishes the increase in apoptosis. Strikingly, in osteocytic MLO-Y4 cells the proapoptotic effect of glucocorticoids is preceded by cell detachment due to interference with FAK-mediated survival signaling generated by integrins. In this mechanism, Pyk2 (a member of the FAK family) becomes phosphorylated and subsequently activates proapoptotic JNK signaling. The proapoptotic actions of glucocorticoids may involve suppression of the synthesis of locally produced antiapoptotic factors including IGF-1- and IL-6-type cytokines, as well as MMPs, and stimulation of the proapoptotic Wnt antagonist SFRP-1.

Regulation of bone formation by osteocytes: sclerostin

Osteocytes express sclerostin, the product of the *Sost* gene, which antagonizes several members of the BMP family of proteins and also binds to LRP5/LRP6, preventing canonical Wnt signaling. Loss of *Sost* in humans causes the high-bone-mass disorders van Buchem syndrome and sclerosteosis. In addition, administration of an antisclerostin antibody increases bone formation and restores the bone lost after ovariectomy. Conversely, transgenic

Fig. 6.7 Osteocytes sense the need for bone resorption and send signals to lining cells, which retract from the bone surface and form a canopy under which remodeling occurs, called the *bone-remodeling compartment* (BRC). Osteoclast precursors are transported to the BRC by marrow capillaries, differentiate to mature osteoclasts under the influence of pro-osteoclastogenic and antiosteoclastogenic cytokines (receptor activator of nuclear factor- κ B ligand [RANKL], macrophage colony-stimulating factor [M-CSF], and osteoprotegerin [OPG]) derived from osteocytes, and initiate bone remodeling. Osteoblast precursors from the bone marrow or the circulation differentiate into mature, bone-synthesizing cells in response to factors released from the bone matrix by resorption. Differentiation and function of osteoblasts is controlled by molecules derived from osteocytes, including sclerostin and Dkk-1. (From Bellido T, Plotkin LJ, Bruzzaniti A. *Bone cells*. In: Burr DB, Allen MR, editors. *Basic and applied bone biology*. San Diego: Academic Press; 2014, p. 27-46, Figure 10.)

mice overexpressing Sost exhibit low bone mass.⁴³ These lines of evidence demonstrate that sclerostin derived from osteocytes exerts a negative feedback control at the earliest step of mesenchymal stem cell differentiation toward the osteoblast lineage. Moreover, PTH and mechanical loading downregulate the expression of sclerostin in osteocytes, which reveals a novel mechanism of bone anabolism triggered by osteocytes.

Regulation of bone resorption by osteocytes: RANKL and osteoprotegerin

The cues that signal bone resorption are not completely understood. Apoptotic osteocytes could regulate the recruitment of osteoclast precursors and their differentiation in two ways. Osteocyte apoptosis may indirectly stimulate osteoclastogenesis by inducing stromal/osteoblastic cells to secrete RANKL. In addition, osteocytes can directly secrete RANKL. Indeed, *in vitro*, purified osteocytes express higher levels of RANKL than osteoblasts and bone marrow stromal cells. The severe osteopetrotic phenotype observed in mice lacking RANKL in osteocytes and their resistance to bone loss induced by tail suspension strongly suggests that osteocytes are a major source of RANKL *in vivo*. Osteocytes also secrete OPG, which, as in osteoblasts, is regulated by the Wnt/ β -catenin pathway. Mice lacking β -catenin in osteocytes are osteoporotic due to increased osteoclast numbers, whereas osteoblast function is normal. Emerging evidence also points to osteocytes as an additional source of secreted M-CSF in bone. Together, these new findings suggest that osteocytes control the bone-remodeling process by regulating osteoclast and osteoblast differentiation and function.

Osteocytes and the bone-remodeling compartment

Lining cells play an important function in initiating bone remodeling by retracting from quiescent bone surfaces and creating a canopy over osteoclasts and osteoblasts in the bone multicellular unit.⁴⁴ On the endocortical surface, this canopy presumably encases bone marrow osteoblast precursors and is penetrated by blood vessels that provide hematopoietic osteoclast progenitors. The lining cell canopy, associated capillaries, osteocytes, osteoclasts, and osteoblasts form a compartment, the bone-remodeling compartment (BRC), which is separated from the rest of the marrow and which can sequester molecules that regulate the cells that remodel bone (Fig. 6.7). The signals that trigger lining cell detachment to form the BRC in a particular bone area are unknown. Premature apoptosis of osteocytes has been shown to precede osteoclast accumulation and resorption,⁴¹ which raises the possibility that osteocytes release molecules that induce lining cell retraction facilitating access of osteoclast precursors to bone surfaces. However, the molecular entities responsible for this purported osteocytic function remain unknown. As discussed earlier, osteocytes express M-CSF⁴⁵ which stimulates proliferation of preosteoclasts, and RANKL,^{46,47} the master cytokine

TABLE 6.1

Dynamic processes of skeletal development and adaptation

Process	Mechanism	Morphology	Function
Growth	F	Woven, lamellar	Increased mass
Modeling	A-F	Primary lamellar	Net increased mass or Adaption of architecture
	A-R	Control of drift and curvature	
Remodeling	A-R-F	Secondary lamellar (osteons, hemi-osteons)	Bone maintenance Repair of microdamage Prevention of bone loss
Repair	F	Woven Rapid mechanical adaptation	Repair of fractures

A, activation; F, formation; R, resorption.

inducer of osteoclast differentiation, both of which could reach the BRC. Factors released from the bone matrix upon resorption, in turn, stimulate osteoblastogenesis. It is also likely that osteocyte-derived sclerostin reaching the BRC through the canalicular system, and secretion of the other Wnt antagonist Dkk-1 by osteocytes as well as osteoblasts, influence the rate of bone formation, providing an additional level of control of osteoblast activity. Based on these lines of evidence, the BRC might provide a supportive environment for differentiation of osteoclast and osteoblast progenitors. Thus, regulation of the bone-remodeling rate by hormonal and mechanical stimuli could be accomplished by controlling the balance between resorption and formation within the BRC through the regulation of osteocytic molecules, including sclerostin, RANKL, and OPG.

GROWTH, MODELING, REMODELING, AND REPAIR

Four dynamic processes are involved in skeletal development and adaptation. These are defined by the relationship of bone resorption and bone formation to each other (Table 6.1). These mechanisms include a

coordinated system that first involves the activation (A) of cell populations, followed by the resorption (R) of preexisting tissue and/or the formation (F) of new or replacement tissue. Bone growth serves to increase bone mass through bone formation. Resorption of bone is not part of the growth process, and the function of growth is only to increase mass, not to adapt the developing structure to its mechanical needs. Growth can occur on a substrate but may involve ossification directly from fibrous tissue (intramembranous bone formation) or by formation of a model with cartilage first and then replacement of the cartilage with bone (endochondral ossification). Modeling uses the tissue formed during the growth process to further increase bone mass and to shape its geometry to mechanical needs. Modeling occurs through the activation of cells followed by either formation or resorption. Formation and resorption are coordinated processes in modeling, but do not occur sequentially on the same surface of bone. Remodeling, on the other hand, is defined by the sequential processes on the same bone surface of activation-resorption-formation (the A-R-F sequence). The function of remodeling is bone maintenance, not increase in bone mass. Bone remodeling is also involved in skeletal repair of microdamage. Bone's repair function, which restores its mechanical properties following a complete fracture or trabecular microfracture, usually occurs through the process of endochondral ossification, which forms a cartilage callus that also includes woven bone to bridge the fracture gap. This is eventually replaced through remodeling with replacement by lamellar bone.

Growth, modeling, and remodeling are present concurrently in all growing children. When skeletal maturity is reached, growth naturally stops. Modeling slows down or stops but may still be present at a reduced rate on trabecular surfaces and on the periosteal surface of the bone. However, at maturity, the predominant process is bone remodeling, which serves to maintain the bone that has been formed and to repair microscopic damage that may be sustained in bone during normal daily activities. Dysfunction in the remodeling process is associated with the loss of bone found in osteoporosis.

Growth

Growth of bone can occur through two different skeletal processes, one involving formation of bone from fibrous membranes and the other involving the formation of a skeletal anlage, or model. Intramembranous bone formation occurs at centers of ossification via direct mineralization in highly vascular fibrous tissues through the action of mesenchymal cells. The calvaria of the skull is the best example of intramembranous bone formation, with the individual bones of the skull acting as centers that eventually grow together at the sutures. Apposition of bone on the periosteal surface of long bones can also occur through intramembranous ossification and has been demonstrated especially in the region of the femoral neck.⁴⁸

In the long bones development generally occurs by the initial condensation of mesenchyme or hyaline cartilage in the form of the eventual skeletal structure. This cartilage model mineralizes over time and becomes detectable as a primary center of ossification. Some bones are formed from a single ossification center, although most of the long bones form secondary centers of ossification at the ends (epiphyses), which eventually fuse to the bone that developed from the primary ossification center (diaphysis) (Fig. e6.2). The secondary centers allow growth to occur at a cartilaginous growth plate until skeletal maturity in the late teens or (for the vertebral bodies) in the early part of the third decade. The growth plate slowly converts into primary spongiosa that become remodeled into lamellar trabecular plates in the metaphysis of the bone.

Modeling

Long bones must grow both in length and in diameter (Fig. 6.8). At the ends of the long bones—near the epiphyses—growth of bone demands that the wider joint surface continually be reshaped and narrowed as it moves down into the metaphysis and diaphysis. Modeling is a continuous and prolonged process—unlike remodeling, which is episodic—and involves a coordinated process of bone resorption on some surfaces, while other surfaces undergo bone formation. Bone modeling occurs on both periosteal and endocortical envelopes, and sculpts bone shape while allowing for expansion of the marrow cavity and periosteal diameter of the diaphysis. At the metaphysis, this occurs by osteoclastic resorption on the periosteal surfaces. As growth continues, however, bone is added to the periosteal surface by osteoblasts and simultaneously removed from the endocortical surface by osteoclasts. This increases whole-bone diameter and expands the marrow cavity, necessary for the formation of blood. It serves a second purpose: to increase the mechanical strength of the bone, while at the same time not increasing its mass or weight at the same rate. Bone curvature is also

THE METAPHYSEAL CUTBACK THAT OCCURS THROUGH MODELING PROCESSES DURING GROWTH TO SHAPE THE BONE

Fig. 6.8 During growth, metaphyseal bone is removed by modeling processes to shape the bone. Subsequent enlargement of the diaphysis occurs through direct periosteal apposition, which is often accompanied by resorption on the endocortical surface to enlarge the marrow cavity. Bone can also change its location and curvature through “drift.” Arrows indicate direction of drift, with smaller circular cells representing osteoblasts and bone formation, and larger ellipsoidal cells representing osteoclasts and bone resorption. (From Martin RB, Burr DB, Sharkey NA. *Skeletal tissue mechanics*. New York: Springer; 1998, p. 62, Figure 19, with permission.)

adjusted during growth through a process known as *drift*, in which the periosteal surface on one side of the bone is undergoing apposition while the other is undergoing resorption. Likewise, different portions of the endocortical surface are undergoing formation or resorption in coordination to maintain the cortical thickness of the diaphysis.

Remodeling

The quantum concept of bone-remodeling states that bone is replaced in packets through the coupled activity of osteoclasts and osteoblasts. The coupling between osteoclasts and osteoblasts is the reason that it was difficult for so many years to control the processes involved in bone loss. When bone resorption is suppressed, formation is also suppressed because these activities are linked by intercellular signaling mechanisms that are still little understood. In remodeling, bone resorption and bone formation are coupled, but in fact may not be balanced. Coupling and balance are not the same; *balance* refers to the relationship between the amount of bone resorbed and the amount formed, whereas *coupling* denotes only that the processes are linked in some way. Bone resorption and bone formation are in balance in the healthy skeleton, but when these are out of balance the amount of bone that is resorbed can be either greater or less than the amount that is subsequently formed. Thus, even though cells are coupled, bone can be lost or added in several different ways based on the altered balance of resorption and formation. In actuality, one almost never finds a balance in favor of bone formation in a remodeling system, although this has been shown to occur with anabolic treatments for osteoporosis, such as the intermittent administration of recombinant human PTH(1-34) (Forteo).⁴⁹ More often, the balance is in favor of resorption. This is the case in osteoporosis, in which global resorption is increased but formation at each of the erosion sites is normal or reduced, which leads to a deficit in bone mass.

This coupled system is termed a *bone multicellular unit* (BMU) because different cell populations are involved. A BMU typically consists of about

Fig. e6.2 Bone consists of the diaphysis (shaft), the metaphysis, and the epiphysis. In growing children, the growth (epiphyseal) plate separates the epiphysis from the metaphysis. During growth, the periosteal surface of the metaphysis must be constantly resorbed, while concurrent bone formation occurs on the endocortical surface, to convert the thin-walled but flared metaphysis into the narrower but thicker-walled diaphysis (McNeal tetrachrome stain).

Fig. 6.9 The entire bone-remodeling sequence, not including mineralization, takes about 4 months in people. There are many cellular processes that occur during each part of the activation-resorption-formation (A-R-F) sequence of events. The amount of resorption and formation are determined both by the individual activity of the cells and by the duration of the cells' lifetime. In cross section, formation requires about four times longer than the resorption of the same amount of bone, and consequently there are many more osteoblasts in bone than osteoclasts. (From Burr DB. *Orthopedic principles of skeletal growth and remodeling*. In: Carlson DS, Goldstein SA, editors. *Bone biodynamics in orthodontic and orthopedic treatment*. Craniofacial Growth Series, vol. 27. Ann Arbor, Mich.: Center for Human Growth and Development of the University of Michigan; 1992, p. 15-50.)

10 osteoclasts and several hundred osteoblasts. When cut in longitudinal section, the BMU shows the sequential aspects of the A-R-F system and the various cell populations that are involved (Fig. e6.3). Each of the phases in this sequence is location, magnitude, and rate specific, so that alterations in the magnitude or timing of one can produce morphologic features characteristic of specific skeletal abnormalities (Fig. 6.9). Activation is initiated by chemical or mechanical signals but actually involves a series of events that include recruitment of precursor cells, differentiation and proliferation of cells, and migration to the site of activity. In humans, these processes take about 5 to 10 days. Bone resorption by mature osteoclasts takes about 3 weeks at a given site, although osteoclasts moving longitudinally through bone at a rate of about 40 $\mu\text{m}/\text{day}$ may live much longer than this. There is a period of reversal during which there is neither bone resorption nor formation; this may represent a period like the activation period during which osteoblasts are undergoing differentiation and proliferation from their precursors. This is followed by a period of bone formation that lasts about 3 months. As unmineralized bone—or osteoid—is laid down, it subsequently begins to mineralize, quickly at first, and then more slowly over the following year. This sequence of events occurs on all four skeletal envelopes (periosteal, endocortical, trabecular, and intracortical).

Changes in bone mass can occur simply through changes in activation frequency. Changes in activation frequency may lead only to transient changes in bone mass if resorption and formation are in balance. Early losses of bone mass due solely to increased activation frequency may resolve after several months as the newly resorbed sites are refilled. Likewise, bone mass may change because some aspect of the recruitment, proliferation, migration, or differentiation of either osteoclasts or osteoblasts is interrupted. These changes may be manifest as alterations of resorption-formation balance but may be caused by activation defects during cell maturation.

Repair

Fracture healing involves several stages in the repair (or regeneration) process (Fig. 6.10). The injury is typically followed by the development of a hematoma with associated inflammatory responses. This phase is followed within a week or so by a regenerative phase characterized by the formation of a cartilage callus. Also, there is direct woven bone apposition on periosteal surfaces through a process typical of intramembranous ossification. This unites the two ends of the bone to stabilize the fracture, but the bone is still not mechanically adapted to normal loads and may be quite weak. The callus subsequently matures to primary bone over a period of months via processes like those involved in endochondral ossification.

Over time, the cartilage callus remodels via the A-R-F sequence of events to become lamellar bone, and eventually the bone is reshaped through modeling processes to achieve something close to its original dimensions. When this process is complete the bone will be geometrically and mechanically similar to its prefracture state.

The rate and extent of healing is dependent on the fracture and also on the mechanical environment. Large amounts of motion increase the size of the cartilage callus and interrupt its remodeling to bone. Small amounts of motion and juxtaposition of the fractured ends of the bone can allow healing without the development of much, or any, callus. Small loads also facilitate healing. There are a variety of local factors that can influence healing. Non-unions can occur if early signals for repair (e.g., from TGF- β and other growth factors and cytokines) are not received, if there is compromise to the local blood supply, or if there are complicating factors due to infection or bone death caused by radiation or thermal injuries. Comorbid conditions (e.g., poor diet, smoking, calcium or vitamin D deficiencies, and excessive alcohol intake) can prolong the time required to heal a fracture.

Fig. e6.3 A bone multicellular unit, or BMU, is shown. This system shows the sequential aspects of the activation-resorption-formation (A-R-F) system, and the various cells that are involved. At the head of the resorption front (also called the *cutting cone*), there is a capillary bud, which supplies nutrients to the multicellular osteoclasts that are decalcifying and resorbing bone matrix. Behind the resorption front, teams of osteoblasts are lined up along the wall of the BMU, laying down new bone, or osteoid, that will subsequently become mineralized. Some of these osteoblasts will eventually embed themselves and become terminally differentiated osteocytes (McNeal tetrachrome stain).

Fig. 6.10 An injury to bone is typically followed by the development of a hematoma with associated inflammatory responses. This phase is followed by the development of a periosteal bridging callus (at least in separated and unstable fractures) that is composed of calcified cartilage. Over time, this cartilage callus remodels to become bone, and eventually the bone is reshaped through modeling processes to achieve something close to its original dimensions. Tendons and ligaments

■ GRAHAM RILEY

- Although tendons and ligaments generally respond similarly to injury, there are anatomic and regional differences in the speed and quality of repair.
- Chronic painful conditions are more common in tendons, but some ligaments may also be affected.
- Most chronic conditions are degenerative and associated with “overuse.”
- Although inflammatory cells are not usually found in chronic lesions, various inflammatory mediators are present both in and around the affected tissue.
- Many current therapies for chronic conditions are not supported by good clinical trials.
- Future therapies in development include the use of mesenchymal stem cells to promote better-quality repair and regeneration of the extracellular matrix.

INTRODUCTION

Tendons and ligaments are dense fibrous connective tissues that are essential for joint movement and stabilization. They have a similar composition and structure and are composed primarily of a hierarchic arrangement of collagen fiber bundles primarily aligned with the long axis of the tendon. They are metabolically active and capable of responding to extrinsic factors such as mechanical load, exercise, and immobilization. However, there are differences in structure, composition, and function between tendons and ligaments that make it unwise to extrapolate directly from one tissue to another.¹

Both tendons and ligaments are frequently subjected to acute injury as a result of trauma, overload, or direct mechanical insult resulting from crushing blows or penetrating objects. The repair response follows the same general pattern, with the important proviso that some ligaments and tendons are apparently able to mount a more effective repair response than others.² This has been linked to a number of factors, such as whether tendons are intrasynovial or extrasynovial or whether ligaments are intraarticular or extraarticular, and the ability to repair may be dependent on the quantity and quality of the vascular network at different sites. Tendons are more prone than ligaments to chronic, insidious forms of injury. These conditions, best described as “tendinopathies,” are often associated with repeated strain and repetitive microtrauma (“overuse”) rather than a single traumatic episode.^{3,4}

ACUTE TENDON AND LIGAMENT INJURIES

The cellular events occurring after traumatic injury to a tendon or ligament are similar and common to all soft connective tissues.¹ The response is usually divided into three phases, more for convenience because the phases merge imperceptibly into each other and represent a continuum rather than discrete stages. The initial phase, which occurs in the first week after disruption of the tendon fibers, is characterized by inflammation, edema, and infiltration of a variety of cell types attracted to the region by inflammatory mediators. Platelets and mast cells release histamine, a potent agent that promotes vasodilation and increases blood vessel permeability. Serotonin, bradykinin, leukotrienes, and prostaglandins act together to recruit polymorphonuclear leukocytes and lymphocytes from the circulation. Growth

factors released by platelets include platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), and epidermal growth factor (EGF). Macrophages, which are present within 24 hours, phagocytose tissue debris and release numerous inflammatory mediators and growth factors, including basic fibroblast growth factor (bFGF), TGF- α , TGF- β , and PDGF. These growth factors are chemotactic for fibroblasts and other cells and generally act to stimulate matrix synthesis. Angiogenic factors such as bFGF and vascular endothelial growth factor stimulate capillary ingrowth into the fibrous clot. Toward the end of the inflammatory phase, which may last several days, fibroblasts become the predominant cell type. The second phase, generally lasting up to 6 weeks after injury, is characterized by cell proliferation and synthesis of new matrix by fibroblasts. This new matrix is different in both quality and quantity from the normal matrix. Described as granulation tissue, it consists of a disorganized matrix with an elevated cell density that fills the tissue defect. The third phase, which occurs from 3 to 6 weeks after injury and lasts for at least a year, is a prolonged period of remodeling and maturation in which the matrix components and tissue cellularity gradually revert toward normal. During this stage many cells in the scar are contractile myofibroblasts, which are specialized cells important for organization of the wound tissue.

LIGAMENT INJURY AND REPAIR

Although ligaments are generally similar to tendons, the quality of repair in ligaments from different anatomic locations is known to have substantial differences.² Most ligaments, such as the collateral ligaments of the knee, are extraarticular and in close relationship with the joint capsule and adjacent vascular structures. This environment is apparently more conducive to repair than that surrounding the intraarticular cruciate ligaments. Injury to the cruciate ligaments, for example, provokes a profuse vascular response, but healing by second intention (i.e., contraction and filling of the defect by the formation of granulation tissue) does not occur. The medial collateral ligament, in contrast, heals spontaneously without the need for surgical repair. A variety of explanations have been proposed, such as the presence of synovial fluid preventing fibrin clot formation and the more dynamic mechanical environment of the cruciate ligament inhibiting repair. There are also thought to be intrinsic differences in cell types from different ligaments, with differences in morphology as well as in mitogenic, chemotactic, and synthetic responses. Medial collateral ligament fibroblasts, for example, are more proliferative and produce more type III collagen than do cells from the anterior cruciate ligament, and they show a greater response to growth factors such as EGF, TGF- β , and bFGF.⁵

CHRONIC TENDON PATHOLOGY

A variety of different terminologies are used for the chronic pathology that is more commonly seen in tendons, although some ligaments (e.g., the patellar) may also be affected. This confusion is partly due to incomplete understanding of the pathology, as well as difficulty making the diagnosis, because biopsy specimens are rarely obtained at early stages of the disease. Terms such as *tendinitis* imply that inflammation is present, although little evidence of any inflammatory process has been found in histologic studies.⁶ Conditions are consequently best considered as either acute or chronic, whether caused by trauma or repeated microtrauma (often attributed to “overuse”) or the result of an insidious process of clinically silent (i.e., “pain-free”) degeneration. Unless the presence of inflammation or degeneration has been unequivocally demonstrated, most tendon pain and dysfunction are best described as a “tendinopathy.”

Fig. 7.1 Histologic features of tendinopathy. (a) Normal Achilles tendon showing dense bundles of highly organized collagen fiber bundles and relatively few tenocytes arranged in columns (hematoxylin-eosin [H&E]). (b) Specimen from a patient with painful tendinopathy showing increased cellularity and vascularity at the site of the lesion (H&E). (c) Normal Achilles tendon showing a low abundance of proteoglycan (toluidine blue). (d) Specimen from a patient with Achilles tendinopathy showing a much increased abundance of proteoglycan throughout the tendon matrix (toluidine blue). (e) Degenerative supraspinatus tendon specimen from a patient with rotator cuff pathology showing loss of matrix organization, disruptions in fibrillar structure, and reduced cellularity (H&E). (f) Specimen of the supraspinatus tendon from a patient with rotator cuff pathology showing increased proteoglycan associated with rounded cells in a "fibrocartilaginous" matrix (H&E/Alcian blue).

Sites commonly affected by tendinopathy include the supraspinatus and long head of the biceps in the shoulder, the medial and lateral extensors of the elbow, the patellar ligament, the posterior tibialis, and the Achilles tendon. In most cases, with the notable exception of the Achilles tendon, the site affected is at or near the bone insertion. These sites have several common features: they are more highly stressed, are often exposed to repeated strain, including shear or compressive force, and are relatively less vascularized than the tendon midsubstance. The insertion also has a different structure and composition than the midsubstance; it is fibrocartilaginous and contains matrix components that are more commonly associated with articular cartilage, such as type II collagen and aggrecan.⁷ The highly specialized structure is thought to help dissipate the stress and compressive force acting on the insertion site.

ETIOLOGY OF CHRONIC TENDINOPATHY

The cause of chronic tendinopathy is not fully understood, and many different factors have been implicated. Many lesions are associated with a reduction in vascular perfusion, particularly at specific sites in the supraspinatus and the Achilles. Because most tendon ruptures occur in the fifth decade, age-related changes are also implicated; however, rupture of the Achilles tendon is most common in a younger, physically active population. More tendon ruptures tend to occur in males than in females, although it is thought unlikely that this is directly associated with gender because the age and activity level of male and female patients are frequently very different.⁸ The combination of a more sedentary existence with increased leisure time, recreational sports, and a propensity to obesity may account for the greater incidence of tendinopathy in the developed world. A strong association has been found with particular sports and activities that result in high levels of stress being applied to specific sites. Leg-length discrepancies and other anatomic variants, such as the shape and slope of the acromion in the shoulder, are implicated in some individuals. Joint laxity may predispose to some conditions such as rotator cuff lesions. Genetic factors have also been identified, with an increased risk for tendon injury in individuals with specific variants of genes encoding for structural proteins such as collagen type V and tenascin-C.^{9,10}

HISTOPATHOLOGIC FINDINGS

Many histopathologic investigations of tendinopathy have been conducted, usually on specimens taken from either ruptured tendons or chronic painful tendons. Ruptures are frequently described as "spontaneous," which means that the rupture occurred without any preceding clinical symptoms, although underlying degeneration of the extracellular matrix is almost always present.⁶ Painful tendons frequently do not progress to frank rupture, and specimens are generally obtained from patients who have failed prolonged conservative treatment before surgery, at which time a specimen was removed for analysis. Painful tendons generally show increased cellularity, cell rounding, increased glycosaminoglycan (GAG) content ("mucoid degeneration"), decreased matrix organization, and increased blood vessel infiltration (Fig. 7.1). Ruptured tendons show similar degenerative features of the extracellular matrix, although cellularity is generally reduced and there is often little evidence of neovascularization. The cell changes in ruptured tendons are consistent with hypoxia, and calcific deposits and lipid droplets are frequently found in the matrix.⁶ The calcification seen in many ruptured tendons is thought to be a degenerative phenomenon that occurs as a result of precipitation of calcium salts nucleated by cell debris or matrix constituents,¹¹ although a cell-mediated process similar to endochondral ossification has been identified in some pathologic tendons.¹² Apoptosis (programmed cell death) is increased significantly in both patellar tendinopathy and ruptured supraspinatus tendons.^{13,14} Most cells in painful tendinopathy specimens are fibroblast-like, albeit generally more rounded or ovoid, and there is an absence of inflammatory cells, at least in the tendon substance. Overall, the histopathologic findings in most cases of tendinopathy are consistent with matrix degeneration, and in painful tendons the cellular and vascular response suggests at least some attempt at repair. Some evidence suggests that the cellular changes, such as the rounder appearance and increased number, occur before any clinical symptoms become apparent.¹⁵

Extracellular matrix changes in tendinopathy

The extracellular matrix of tendons consists mainly of the structural protein collagen, which accounts for approximately 65% of the dry weight.¹ Around

TABLE 7.1
Changes in the extracellular matrix in painful tendinopathy

Molecule	Potential significance
Collagen type I (mRNA) ↑	Attempted repair/adaptation ^{16,17}
Total collagen (protein) →	No significant tendon growth or adaptation ^{18,19}
Collagen type III (mRNA/protein) ↑	Fibrosis/scar formation ¹⁸ Smaller-diameter fibrils ¹⁶ Decreased fibril strength ²⁰
Fibronectin (mRNA) ↑	Repair response? ¹⁶ Altered cell-matrix interactions ²¹
Tenascin-C (mRNA/protein) ↑	Repair response? ²² Altered cell-matrix interactions ¹⁶
Glycosaminoglycan (sugar moiety) ↑	Fibrocartilaginous change ²³ Resistance to compression ¹⁹
Aggrecan (mRNA/protein) ↑	Fibrocartilaginous change ²⁴ Resistance to compression ¹⁹
Biglycan (mRNA/protein) ↑	Fibrocartilaginous change ²⁴ Resistance to compression ¹⁹
Fibromodulin (protein) ↑	Modulation of collagen fibril formation and fibril diameter ¹⁹
Versican (mRNA/protein) ↑ →	Increased or no change ¹⁶ Significance not known ¹⁷
HP/LP collagen cross-links ↑	Fibrosis/scar formation ¹⁹ Adaptation to increased load? ²⁵
Pentosidine (AGE) ↓	Replacement of mature collagen and increased matrix remodeling ²⁵

Arrows indicate the direction of change (→ indicates no change).

AGE, age-related glycation end product; HP, hydroxyprolydinaline; LP, lysylpyridinaline.

95% is type I collagen, with lesser amounts of collagen types II, III, IV, V, VI, IX, XII, and XIV. In tendinopathy, numerous molecular changes have been identified, consistent with the hypothesis that dynamic changes in the regulation of matrix turnover by the resident tenocytes are responsible for the altered tendon function (Table 7.1). The level of expression of some collagen genes changes, and increased amounts of collagen type III are found throughout the tendon matrix, not just restricted to the endotenon as in normal tendons.¹⁷⁻²⁰ Similar changes are found in scar tissue or pathologic fibrosis and have implications on the strength of the tendon because type III collagen tends to form heterotypic fibrils with type I collagen, which has a smaller average diameter and forms a meshwork rather than closely aligned fibril bundles. There are also increases in type V collagen, an increase in denatured collagen, and substantial changes in the cross-links that stabilize the collagen matrix.²⁰⁻²⁴ Strong evidence has shown increased turnover of the collagen matrix in tendinopathy because the collagen carries less of the glycation product pentosidine, which accumulates on long-lived matrix proteins with age.²⁵⁻²⁷ There are also differences between tendons, with evidence of higher rates of collagen turnover in the supraspinatus tendon than in the biceps brachii tendon in the forearm in association with the increased prevalence of tendon injury and pathology in the shoulder, although whether this is cause or effect remains to be established.

Though less abundant than collagen, proteoglycans are important constituents of the tendon matrix and have a range of important functions, including water retention, sequestration of growth factors, and mediation of cell-matrix interactions.¹ A diverse family of molecules, they all contain at least one chain of a repeating disaccharide GAG. Small leucine-rich proteoglycans (SLRPs) such as decorin, fibromodulin, biglycan, and lumican are present in normal tendons, and they function to modulate fibril growth, diameter, and organization, as well as bind growth factors such as TGF- β . The large proteoglycans versican and aggrecan are also present, although aggrecan is more abundant at the insertion or at sites where the tendon is subject to compression.⁷ The large proteoglycans, aggrecan in particular, carry more GAG chains than the SLRP, and the high negative charge density of the sulfated GAG holds water in the tissue, which is important for its viscoelastic properties and resistance to shear or compressive load. In tendinopathy, one of the most frequent observations is increased GAG in the matrix, often associated with rounded cells.²⁸ The identity and processing

of the particular proteoglycan associated with the GAG have not been fully characterized at the protein level, although molecular analysis has shown increased expression of genes encoding for aggrecan and biglycan, even in the midsubstance of the Achilles tendon, where fibrocartilage is not normally found.²⁴ These changes are consistent with an adaptive response to shear or compression, thus suggesting that at least some of the molecular alterations are the result of changes in the level and direction of mechanical forces acting on the resident tendon cells (tenocytes). Although most tendinopathies are reported to have similar molecular changes, some differences can be noted. For example, levels of gene expression for the large proteoglycan versican were reported to be unchanged in painful Achilles tendons,¹⁷ even though increased versican has been reported in patellar tendons.²⁹

Other constituents of the tendon matrix have received relatively little attention in studies of tendinopathy. Fibronectin, a large multidomain glycoprotein that can form many different interactions with cells and other matrix molecules, is of very low abundance in normal tendon.³⁰ The large increase reported in ruptured Achilles and supraspinatus tendons is consistent with a role in the repair response, where fibronectin is involved in cell adhesion and migration at the wound site. Tenascin-C, a multimeric glycoprotein that may function to help organize the matrix, is abundant in normal tendon but is increased in tendinopathy.²² There are changes in splice variant expression and a strong association of tenascin-C with the rounded cells in the pathologic tendon. In addition, there is evidence of enzyme-mediated degradation of tenascin-C in rotator cuff disease, consistent with the increased matrix remodeling associated with the condition.

Matrix turnover and remodeling

Matrix degradation, both in health and disease, is to a large extent mediated by a family of enzymes known as matrix metalloproteinases (MMPs). Humans have 23 MMPs and a family of four naturally occurring inhibitors known as tissue inhibitors of matrix metalloproteinases (TIMPs). These enzymes have a variety of different substrate specificities, with activity against all the different structural matrix components, although they are also involved in the processing and activation of growth factors and their receptors and implicated in the control of cell activity, as well as in matrix degradation. In tendinopathy, the expression and activity of various MMPs and TIMPs exhibit changes consistent with increased proteolytic activity and turnover of the matrix. For example, ruptured rotator cuff tendons showed greatly increased collagenase (MMP-1) activity and reduced gelatinase (MMP-2) and stromelysin (MMP-3) activity in comparison to normal tendons, and these changes have been correlated with high levels of collagen turnover.²⁵ A study of gene expression in Achilles tendons showed that painful and ruptured tendons have distinct patterns of expression consistent with quantitative and qualitative differences in catabolic activity in the different clinical entities.³¹ Ruptured tendons showed higher levels of expression of MMP-1, MMP-9, MMP-19, MMP-25, and TIMP-1 and lower levels of MMP-3, MMP-7, TIMP-2, TIMP-3, and TIMP-4. Painful tendons displayed reduced expression of MMP-3, MMP-10, and TIMP-3 and increased expression of A disintegrin and metalloproteinase-12 (ADAM-12) and MMP-23. Very little is known about the role and function of ADAM-12 and MMP-23 in tendons, although both have been associated with changes in cell phenotype: ADAM-12 with myogenesis and lipidogenesis and MMP-23 with endochondral ossification.^{32,33} In summary, the changes in tendon matrix composition are consistent with the changes in cell-mediated matrix remodeling that precede the onset of clinical symptoms, and these changes are mediated at least in part by metalloproteinases.

Mechanical strain and regulation of cell activity

The cellular and molecular processes driving the changes in tendon matrix remodeling in tendinopathy have yet to be determined. It is uncertain to what extent remodeling of the tendon matrix represents a limited (or potentially failed) repair response to microscopic fiber damage or an adaptive (or potentially maladaptive) response to changes in cell loading. Cyclic tensile loading of tenocytes *in vitro*, simulating overuse, has been shown to elicit the expression of several inflammatory mediators and growth factors, as well as metalloproteinase enzymes, and it has been suggested that this may trigger neovascularization, inflammation, and increased proteolytic activity in the tendon.³⁴ However, the levels of strain required to elicit this response are high, potentially much higher than the strain experienced by cells in

TABLE 7.2
Changes in cytokines and signaling molecules in painful tendinopathy

Molecule	Potential role/significance
TGF- β $\uparrow$	Repair/growth/fibrosis ³⁶ Matrix synthesis ³⁷
VEGF $\uparrow$	Associated with angiogenesis and neovascularization ^{38,39}
IL-1 $\uparrow$	Inflammation in surrounding tissues (bursa, synovium) ^{40,41}
IL-6 $\uparrow$	Inflammation within tendon ⁴²
IL-15 $\uparrow$	Inflammation within tendon ⁴²
IL-18 $\uparrow$	Inflammation within tendon ⁴²
COX-2 $\uparrow$	Production of prostaglandin within and around tendon ³⁷
Glutamate $\uparrow$	Neurotransmitter—associated with pain and/or apoptosis ^{43,44}
Substance P $\uparrow$	Neurotransmitter—associated with pain perception and edema ⁴⁵
PGE ₂ $\rightarrow$	Mediator of pain and inflammation ^{43,44}
PDGFR $\uparrow$	Mediates cell response to PDGF—cell proliferation ⁴⁶
NMDAR $\uparrow$	Glutamate receptor—effect on tendon cell not known ⁴³
TGF β R1 $\downarrow$	Mediates cell response to TGF- β —possible reduced response and poor repair ³⁶

vivo. More recently, it has been shown that when released from tension, tenocytes will upregulate their expression of the collagenase MMP-13 and that this typically occurs after failure of one or more of the tendon fiber bundles in the stretched tendon.³⁵ Thus, it appears that MMP output is attenuated by normal loading conditions and that damage to tendon fibers releases the cells from this strain regulation, which results in increased collagenase expression and the potential for matrix degradation.

Inflammation and inflammatory mediators in tendinopathy

Although inflammatory cells are absent, this does not mean that inflammatory mediators are not implicated in tendinopathy, at least at some stage in the disease, and changes in a number of cytokines, growth factors, and signaling molecules have been detected in tendinopathy (Table 7.2). Increased levels of interleukin-1 (IL-1) have been detected in tissues surrounding painful tendons, such as the bursa in the shoulder.^{40,41,47} Prostaglandin E₂ and other inflammatory mediators such as thromboxane, bradykinin, and IL-6 are increased in peritendinous tissue after prolonged periods of intense exercise.⁴⁸ Levels of growth factors such TGF- β and insulin-like growth factor 1 (IGF-1) are also increased, and these factors have been shown to have a stimulatory effect on collagen synthesis.^{48,49} However, some or all of these changes may be part of the adaptive response or be involved in tissue repair, and their precise contribution to the pathology is uncertain.

Pain and neuropeptides

Pain in tendinopathy has been associated with the ingrowth of nerve endings and release of neurotransmitters such as substance P, calcitonin gene-related peptide, and glutamate.⁴³⁻⁴⁵ Levels of substance P were increased in the subacromial bursa fluid of patients with rotator cuff tendinopathy and correlated with the degree of pain during motion.⁴⁵ Apart from modulation of pain, substance P and other neuropeptides regulate the local circulation and may also directly affect tenocyte activity, as well as mediate neurogenic inflammation, thereby potentially accounting for the bilateral occurrence of tendinopathy in many patients. Consequently, antagonists of neuropeptides and neurotransmitters such as glutamate have been proposed for the treatment of tendinopathy.⁵⁰ However, nerve ingrowth and increased expression

of neuropeptides are part of the normal tendon repair response, and injection of substance P has been used for the treatment of tendon injuries because it increases the organization of collagen fibrils and the strength of the repair.⁵¹

TREATMENT OF TENDON AND LIGAMENT PATHOLOGY

A great variety of treatments have been used for acute and chronic tendon and ligament injuries, although relatively few have shown clinical benefit in properly controlled clinical trials.⁴ Injection of a sclerosant to target the neovascularization seen in tendinopathy is advocated by some practitioners,⁵² although there is some concern that the vascular response is part of the repair process and may have negative consequences in the long term.

Nonsteroidal antiinflammatory drugs (NSAIDs) are often used for ligament and tendon injuries and may be of some benefit in managing pain in chronic tendinopathies. Their pharmacologic target is cyclooxygenase (prostaglandin synthase), a key enzyme in the formation of prostaglandins, which are mediators of pain and inflammation. Studies of their effects on tendon healing have been inconclusive, with both positive and negative effects being reported. However, because cyclooxygenase-2 was shown to be increased in patellar tendinopathy⁵³ and prostaglandin injected around a tendon can induce a form of degenerative tendinopathy,⁵⁴ a rational basis may exist for the use of NSAIDs, at least in some patients.

Corticosteroid injection is a common treatment of chronic tendon lesions despite limited evidence to strongly support its use, and any benefit achieved is usually short term. Many case reports have described rupture, often bilateral, of the Achilles and other tendons after long-term oral corticosteroid treatment and also after local injections. Ruptures are associated with reduced collagen content and decreased mechanical strength, presumably as a result of the suppression of collagen synthesis and turnover.

Controlled-motion therapy for acute tendon and ligament injuries is now generally accepted and also used for the treatment of chronic tendinopathies, particularly in the form of high-loading eccentric exercises.⁵⁵ It is well known that prolonged immobilization has deleterious effects on the quality of repair, in addition to other complications such as muscle atrophy, joint stiffness, cartilage deterioration, adhesions, and thrombosis. Tension, applied cyclically or as a constant load, has a positive influence on the intrinsic fibroblast response and the strength of repair. It promotes cell proliferation and migration, facilitates the alignment of fibroblasts, and increases collagen synthesis, presumably mediated by the stimulation of growth factors such as IGF-1, TGF- β , and connective tissue growth factor in and around the tendon.⁴⁸ More experimental work and controlled studies are required to define the optimum exercise/loading regimen for promoting reorganization and remodeling of the damaged tissue so that higher strength and better function can be achieved.

CONCLUSION

Ligaments and tendons are similar but not identical; they respond similarly to acute injury, but chronic pain and degeneration are more common in tendons. These tissues are metabolically active and respond to changes in their mechanical and chemical environment, with matrix changes mediated by altered cell synthetic activity and the local production of a variety of matrix-degrading proteases. Injury results in substantial and permanent changes in the quantity and quality of the extracellular matrix. Regional differences in the response to injury are related to tissue cellularity, vascularity, matrix composition, and organization. The repair tissue can be affected and modulated by both physical and chemical factors, although the precise conditions required to optimize repair have not been rigorously defined. In tendons, most pathology is degenerative and results in either a “spontaneous” tendon rupture or a chronic painful tendinopathy, sometimes associated with calcification. Degeneration in tendinopathy has been shown to be an active, cell-mediated process involving increased levels of matrix remodeling, with the increased synthesis and degradation of matrix components mediated by a variety of enzymes. The source of pain in chronic tendinopathy is uncertain because inflammatory mediators may not be present in the tendon, although mediators of pain and inflammation may be increased in the surrounding peritendinous tissue or fluid. Current forms of treatment are based largely on empirical observations, and their effectiveness is in most cases questionable. More clinical and experimental work remains to be done to develop an evidence-based approach to therapy.

Connective tissue responses to mechanical stress

■ DONALD M. SALTER

- Bone, cartilage, tendon, skeletal muscle, and other connective tissue require exposure to physiologic levels of mechanical stress to remain healthy.
- Moderate exercise improves the strength and function of connective tissue.
- Withdrawal of mechanical stimuli or prolonged exposure to excessive mechanical load results in tissue degeneration and the development of diseases such as osteoarthritis.
- Mechanotransduction is the mechanism by which a mechanical signal is recognized by connective tissue cells and translated into biochemical and molecular responses.
- Connective tissue cells express mechanoreceptors that allow recognition of the physiochemical changes that occur within connective tissue during mechanical loading.
- Activation of mechanoreceptors results in the generation of secondary messenger molecules and activation of signaling events that regulate gene expression and control cell function.

Exposure to physiologic mechanical forces is important for the maintenance of most, if not all connective tissues, including bone,^{1,2} cartilage,³ tendon,⁴ and skeletal muscle. Movement and mechanical stimulation are essential for normal embryonic development and morphogenesis of the skeleton and joints. Wolff's law states that bone in a healthy person will adapt to the loads under which it is placed. When loading increases, bone remodels to become stronger to resist that sort of loading, whereas when loading decreases, bone will atrophy because there is no stimulus for continued remodeling, which is required to maintain bone mass. This ability to alter structure in response to mechanical loading is shared with all connective tissue and is referred to as *tissue mechanical adaptation*.

In general, mechanical loading of connective tissue within a physiologic range such as is encountered during normal, everyday activity is sufficient to keep connective tissue healthy. Clinical observations and *in vivo* studies show that moderate exercise increases connective tissue performance. Changes in skeletal muscle bulk and strength are obvious, but other connective tissues are similarly affected. Differences in bone mass in the dominant and nondominant arms of tennis players who start training before puberty are a result of the differences in applied mechanical load.⁵ The mechanical strength and collagen content of tendons are increased by physical exercise,⁶ and exercise promotes proteoglycan synthesis and increases the thickness of articular cartilage.⁷ In contrast, withdrawal of mechanical stimuli results in connective tissue atrophy, as evident in paraplegics, patients undergoing prolonged bed rest, and astronauts. The bones in paralyzed and underused limbs are architecturally and mechanically inferior to those subjected to normal mechanical loading. Similarly, immobilization results in major loss of the mechanical properties of tendons,⁸ and significantly, both overloading and underloading of articular cartilage are associated with loss of cartilage matrix and the development of osteoarthritis.⁹

MECHANOSENSITIVE CONNECTIVE TISSUE CELLS

For tissue adaptation to occur in response to applied mechanical forces, cells within connective tissue need to receive information from their environment

and modify the environment appropriately to the mechanical stress to which it is exposed. This process can be divided into four main phases (Fig. 8.1)¹⁰: (1) macroscopic forces are translated into local action at the surface of the mechanosensitive cell—mechanocoupling; (2) forces are transduced from the exterior of the mechanosensitive cell into biochemical signals within the cell—mechanotransduction; (3) signal transmission from the mechanosensitive cell to effector cells; and (4) extracellular matrix (ECM) modeling/remodeling. Most connective tissue cells are mechanosensitive. In cartilage, chondrocytes both sense mechanical stimuli and act as effector cells that produce the matrix macromolecules and proteases required for tissue turnover and homeostasis. Tenocytes have a similar role in mechanical tissue adaptation in tendons.¹¹ In bone the situation is more complex in that multiple cell types are present, including progenitor cells, endothelial cells, and bone-forming and bone-resorbing cells. Nevertheless, there is growing consensus that osteocytes are likely to be the most important mechanosensitive cells in bone remodeling through paracrine effects on cells of the osteoprogenitor and osteoclast lineage.^{1,2}

MECHANOCOUPLING

The mechanical loads applied to connective tissue have been extensively measured *in vivo* and vary in different tissues. In adult bone, peak strain magnitudes of 2000 to 3500 microstrain are encountered during vigorous exercise, whereas in normal activity, magnitudes of less than 10 microstrain occur thousands of times per day. Cartilage and tendon are exposed to much greater loads.¹² Normal walking generates forces three to four times body weight in the hip and knee, which rises to seven times body weight with rapid walking. During standing or climbing stairs, forces up to 20 megapascals are produced in the hip within milliseconds. The Achilles tendon is thought to encounter forces 4 to 12 times body weight during walking and running as the forces generated in muscles are transmitted to bone.¹³ Cells are not directly exposed to mechanical forces because they are surrounded by ECM, which acts to absorb, transmit, and dissipate these forces. Cartilage, for example, contains a type II collagen network that imparts tensile strength, as well as proteoglycan to resist compression, which allows the tissue to withstand high compressive and shearing loads. The forces encountered by cells in most connective tissue are not precisely known.

Dynamic compression of cartilage causes a range of physiochemical changes, including hydrostatic pressure gradients, fluid flow, streaming potentials, and alterations in matrix water content, fixed charge density, mobile ion concentrations, and pH and osmotic pressure, as well as chondrocyte deformation.¹⁴ All these changes may influence cell behavior. Loading of bone induces shear, strain, and compression, with up to 5000 microstrain generated at the osteocyte cell surface¹⁵ and the development of pressure gradients that stimulate flow of interstitial fluid through the osteocytic lacunar network.¹⁶ Osteocytes may encounter much higher levels of strain as flow of interstitial fluid through the canalicular network is resisted by the nonmineralized pericellular matrix and drag forces are induced.¹⁶ In tendon, the complex three-dimensional structure¹⁷ results in a tensile load at the macroscopic level being converted into tensile, shear, and compressive strains encountered by the tenocyte.

MECHANOTRANSDUCTION

Connective tissue cells express mechanoreceptors that recognize the physiochemical changes that occur within connective tissue during mechanical loading. Activation of these receptors results in stimulation of the intracellular signaling cascades that regulate gene expression, changes in

Fig. 8.1 Processes involved in the response of connective tissues to mechanical stimulation.

Fig. 8.2 Mechanical stimuli are recognized by mechanoreceptors that activate a range of intracellular signal pathways, either directly or through autocrine/paracrine signaling. This leads to changes in gene expression and tissue remodeling. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; MAP, mitogen-activated protein; PI3K, phosphatidylinositol-3'-kinase; PKC, protein kinase C; PLC, phospholipase C.

protein expression, and tissue remodeling (Fig. 8.2). A number of molecules and molecular complexes that recognize physicochemical changes, including alterations in cell shape, cell membrane deformation, local ion concentration, and fluid flow, have been identified as candidate mechanoreceptors and include integrins,¹⁸ mechanosensitive ion channels,¹⁹ and connexins.²⁰

Integrins

Integrins are heterodimeric transmembrane glycoproteins that contain α and β subunits. Each α and β subunit consists of an extracellular domain, a single transmembrane region, and a cytoplasmic tail. The extracellular domain provides the binding site for ligands, including fibronectin and

collagen. The cytoplasmic tail is coupled to the cytoskeletal network by focal adhesions, or specialized large macromolecular assemblies that include actin-associated proteins and signaling molecules such as focal adhesion kinase. This enables the integrin receptor to transduce mechanical signals transmitted through the matrix into biochemical responses within the cell. Integrins have been demonstrated to be involved in cellular responses to stretch, elevated hydrostatic pressure, fluid shear stress, and osmotic forces.²¹ Stretch activates integrins and recruits focal adhesion components, which leads to activation of a subset of unoccupied integrins and induces their binding to ECM proteins and stimulation of intracellular signaling. Other mechanical forces may act in a similar way and increase the activation of integrins to stimulate cell adhesiveness and signaling.²² The cytoskeleton also responds to forces channeled through integrins by rearranging its inter-linked actin microfilaments, microtubules, and intermediate filaments. Chondrocytes and bone cells express a variety of integrins, many of which may function as mechanoreceptors. Roles for $\alpha_5\beta_1$, $\alpha_v\beta_5$, and $\alpha_v\beta_3$ have been demonstrated *in vitro*, but $\alpha_5\beta_1$ integrin, the classic fibronectin receptor, appears to be the major integrin mechanoreceptor in connective tissue. The anabolic response of human articular chondrocytes to mechanical stimulation is dependent on $\alpha_5\beta_1$ and involves phosphorylation of focal adhesion proteins.²³ Integrins may be part of larger mechanoreceptor complexes, including accessory molecules such as CD47, that control integrin activation²⁴ and regulate intracellular signaling and gene expression. Conditional knockout of β_1 integrin in cortical osteocytes limits the response of bone to disuse, thus indicating that the β_1 integrins on osteocytes are active in responses of these cells to mechanical loading.²⁵

Stretch-activated ion channels

Stretch-activated or stretch-sensitive ion channels (SACs) open on mechanical deformation of the cell membrane.²¹ Potassium-selective channels (TREK-1 family of 2P domain channels and adenosine triphosphate [ATP]-sensitive potassium channels), the Shaker-IR K^+ channel, the N-type Ca^{2+} channel, ionotropic N-methyl-D-aspartate receptors (NMDARs), and Ca^{2+} -dependent BK channels have all been shown to act as SACs. SACs are directly activated by mechanical forces applied along the plane of the cell membrane. These forces induce membrane tension and distortion of the cell membrane lipid bilayer, which results in conformational changes that alter opening or closing rates and allow ion flux.²⁶ Hydrostatic pressure, in which mechanical forces are applied perpendicular to the cell membrane, appears to be less effective in activating SACs.¹⁹ Opening of calcium-permeable SACs increases intracellular calcium levels and stimulation of downstream calcium-dependent intracellular signal cascades. SACs sensitive to gadolinium are necessary for load-related increases in prostaglandin and nitric oxide (NO) production, cytoskeletal reorganization, and changes in gene expression in response to fluid flow of bone cells and responses of chondrocytes to both strain and compression. The effects of different forms of mechanical stress may be regulated by the activity of voltage-gated or ligand-gated ion channels. L-type calcium channels have roles in bone cell responses to fluid flow rather than to strain, whereas K^+ channels of the TREK family but not gadolinium- or nifedipine-sensitive ion channels are important for stretch-induced elevation of parathyroid hormone-related protein gene expression in bone cells. NMDARs are ligand-gated ion channels that may be involved in chondrocyte mechanotransduction.²⁷

Connexins and primary cilia

Connexins form gap junctions and hemichannels that allow continuity between cells and permit diffusion of ions, metabolites, and small signaling molecules such as cyclic nucleotides and inositol derivatives. They also associate directly with intracellular signaling molecules and regulate cell function through activation of intracellular signal cascades. Connexins are widely expressed in connective tissue, where networks of cells are seen such as in bone,²⁸ tendon,²⁹ and meniscus,³⁰ and probably act to allow propagation of a mechanical stimulus through a tissue. Cx43 is the most abundant connexin family member present in skeletal tissue and is thought to be involved in responses to mechanical loading. Junctional communication between osteocytes modulates shear stress-induced bone remodeling.³¹ In view of the limited cell-cell communication evident in mature articular cartilage, the role of connexins in the mechanical responses of chondrocytes may be to provide communication between intracellular and extracellular compartments and, by release of small molecules such as glutamate and ATP, mediate signal propagation. In tenocytes, Cx32 junctions form a communication network that stimulates collagen production in response to strain, whereas a Cx43 network links tenocytes in all directions and is inhibitory for collagen production.³²

Primary cilia are solitary, immotile cilia present in most cells, including chondrocytes and bone cells, grow from the centrosome, and extend from the cell surface. They contain a variety of cell membrane receptors such as integrins and function as chemosensors or mechanosensors (or as both).^{33,34} Matrix or cell deformation induces bending of the cilium and activation of integrins, SACs, and connexin hemichannels,³⁵ thereby leading to downstream signaling and changes in gene expression.

MECHANICAL STIMULATION-ACTIVATED SIGNALING

Following recognition of the mechanical stimulus, secondary messenger molecules are generated and a cascade of downstream signaling events take place that regulate gene expression and cell function. A wide range of intracellular signaling molecules have been shown to be activated following mechanical stimulation of connective tissue cells. Such molecules include G proteins, protein kinases, and transcription factors that regulate the expression of matrix molecules and proteases involved in tissue remodeling. They may be activated directly as a consequence of mechanoreceptor signaling or indirectly following the production of autocrine/paracrine-acting molecules through rapid production and release of soluble mediators that provide crosstalk between different components of a mechanotransduction cascade and integrate the cellular and tissue response to mechanical stimuli.

G protein-coupled and phosphatidylinositol-3'-kinase-Akt/protein kinase B pathways

Heterotrimeric guanine nucleotide binding proteins (G proteins) are associated with a variety of cell-surface (G protein-coupled) receptors and, depending on the subclass, activate different intracellular signal cascades. G_s induces the formation of cyclic adenosine monophosphate and activation of protein kinase A, whereas G_q and G_o activate phospholipase C, which leads to the production of inositol-triphosphate and diacylglycerol with subsequent release of calcium from intracellular storage sites and activation of protein kinase C (PKC). There is extensive evidence for the roles for these G protein-associated signaling molecules in mechanotransduction but limited evidence for G proteins as mechanoreceptors.

Protein kinase B (PKB)/Akt is a serine/threonine kinase activated by phosphatidylinositol-3'-kinase (PI3K). Mechanical forces activate PI3K via integrin stimulation and, via this route, can inhibit cell death. Inactivation of the PI3K/PKB pathway may be important in the deleterious effects of mechanical overloading of cartilage and bone or tissue atrophy in response to withdrawal of loading.³⁶

Mitogen-activated protein kinases and nuclear factor- κ B

Mitogen-activated protein kinases regulate cellular activities such as gene expression, mitosis, differentiation, and cell survival/apoptosis. ERK1/2, JNK, and p38 have each been shown to be activated in chondrocytes, bone cells, and fibroblasts^{2,37,38} following mechanical stimulation and are of critical importance in the regulation of matrix protein and protease gene expression. Nuclear factor- κ B (NF- κ B) is a protein complex that acts as a transcription factor. In bone cells NF- κ B is directly stimulated by mechanical stimulation through a pathway involving intracellular release of calcium.³⁹

Dynamic biomechanical signals of low physiologic magnitude and mechanical stimulation within the physiologic range block NF- κ B activity and the signaling that promotes chondrocyte responses to proinflammatory cytokines and matrix fragments⁴⁰ and regulation of the proapoptotic or antiapoptotic pathways. Conversely, high-amplitude dynamic stimulation, a catabolic stimulus, induces rapid nuclear translocation of NF- κ B subunits p65 and p50 in a similar manner to interleukin-1 β (IL-1 β).

Prostaglandins, nitric oxide, and adenosine triphosphate

Prostaglandins, predominantly prostaglandin E_2 (PGE $_2$), and NO are rapidly produced when bone cells are mechanically stimulated and are required for the anabolic response of bone to mechanical loading *in vivo*. Prostaglandin production is dependent on integrin; follows the activation of SACs, PKC, and phospholipase A_2 ; and may regulate gap junction activity and expression of receptor activator of NF- κ B ligand (RANKL). In contrast, in cartilage PGE $_2$ is catabolic. Physiologic mechanical loading of chondrocytes inhibits the production of PGE $_2$ and NO, whereas pathologic loading results in release of PGE $_2$.⁴¹ Mechanical loading-induced release of ATP by bone cells and chondrocytes acts through the metabotropic P2Y receptors and P2X receptors expressed by the cells to further regulate the cellular response.

Cytokines and growth factors

IL-4 and IL-1 β autocrine/paracrine activity is seen in the integrin-dependent mechanotransduction cascade of chondrocytes (IL-4 and IL-1 β) and bone cells (IL-1 β) following mechanical stimulation.⁴² In chondrocytes, release of IL-4 relies on secretion of the neuropeptide substance P, which binds to its NK1 receptor. Both IL-4 and substance P are necessary but not sufficient for the increased expression of aggrecan mRNA and decrease in matrix metalloproteinase-3 mRNA induced by the mechanical stimulus, thus suggesting crosstalk with other mechanosensitive signaling pathways. IL-1 β is involved in the early mechanotransduction pathway of both osteoarthritic chondrocytes and human trabecular bone-derived cells. Mechanical loading may also induce the release or activation of sequestered growth factors in the ECM, which will then act on nearby resident connective tissue cells. Basic fibroblast growth factor-2 is a possible mediator of mechanical signaling in cartilage through such a mechanism.

CONCLUSION

Individuals are exposed to a wide range of mechanical stress during daily activity, which is required to maintain connective tissue, including bone, cartilage, and tendons, in a healthy state. Moderate exercise can improve the strength and function of connective tissue, but withdrawal of mechanical stimuli or prolonged exposure to excessive mechanical loads results in tissue degeneration and the development of diseases such as osteoarthritis. The mechanisms by which mechanical stress regulates connective tissue cell function are beginning to be understood. It is likely that identification of mechanoreceptors and mechanotransduction pathways will increase our knowledge of how adverse mechanical environments have detrimental effects on connective tissue and allow the development of novel therapeutic interventions such as mechanomimetics to preserve or reconstitute connective tissue in aging and disease.

Biomechanics of peripheral joints

■ MATTHEW F. KOFF

- Diarthrodial joints in the body act as levers with poor mechanical advantage.
- Joint lubrication is a combination of boundary lubrication, hydrodynamic lubrication, and boundary film lubrication.
- The characteristic stress-strain curve of collagenous tissues, such as tendon and ligament, is an initial toe region followed by a steep linear region before eventual failure.
- Many tissues in the body are viscoelastic and exhibit anisotropic behavior.
- The response of a tissue to an applied load or deformation depends on the tissue's structural composition and fluid content.

INTRODUCTION

Biomechanics is the application of mechanical engineering principles to living organisms. Biomechanics of organisms can be examined at different levels: cellular level (e.g., response of cells to an externally applied force or deformation), tissue level (e.g., strain of the anterior cruciate ligament during normal gait), and whole-joint level (e.g., joint contact forces during activities of daily living).

Engineering principles may be used to understand the cause and progression of many rheumatic diseases. A basic understanding of these principles is beneficial for clinicians and medical professionals. This chapter presents a rudimentary background of engineering mechanics pertaining to whole-joint and tissue mechanics in the human body.

BIOMECHANICS OF WHOLE JOINTS

The effects of a rheumatic disease are often seen at the microscopic level, but the symptoms of the disease are commonly found at the whole-joint level. For example, not only does osteoarthritis cause the formation of clefts and fissures in articular cartilage, but it also produces symptoms including joint pain, stiffness, and reduced range of motion. Examining the transmission of forces through a diarthrodial joint is one way of determining the changing functional capabilities of the joint during the onset and progression of a rheumatic disease.

Statics and dynamics

Whole-joint force analyses are commonly performed to determine the forces that a diarthrodial joint may experience during activities of daily living. A static analysis examines the forces and moments (torques) acting on a body at rest. An example is the evaluation of forces in the knee during standing. In vector notation, this is written as $\Sigma \vec{F} = 0$, $\Sigma \vec{M} = 0$, where $\vec{F}$ are the forces acting on the body and $\vec{M}$ are the moments (torques) acting on the body. A dynamic analysis examines the forces and moments acting on a body in motion. A dynamic analysis includes descriptions of the inertial properties of the body being analyzed. In vector notation, this is written as $\Sigma \vec{F} = m\vec{a}$ and $\Sigma \vec{M} = I\alpha$, where $\vec{a}$ and α are the linear and angular accelerations, respectively, of the body; m is the mass of the body; and I represents the inertial properties (mass distribution) of the body.

An example of a static force analysis is that performed for the shoulder joint. Although this analysis is performed in two dimensions for ease of

analysis, important generalized biomechanical characteristics of whole joints are evident from the results. The goal of this analysis is to calculate the static *in vivo* muscular forces and contact force between the proximal humerus and the glenoid fossa of the shoulder joint. We examine a shoulder at 90 degrees of abduction with a ball held in the hand (Fig. 9.1a).

To perform a force analysis (static or dynamic), it is necessary to construct a free-body diagram, which displays all forces and moments acting on a body or body segment of interest. A free-body diagram of a simplified shoulder joint is shown in Fig. 9.1b. For ease of analysis, the radius, ulna, and humerus have been combined into a single bone segment to represent the arm, forearm, and hand. All forces and moments acting on the selected body segment must be included in the free-body diagram. Forces included in the free-body diagram may be separated into four classes:

1. *Contact force* from the humerus acting on the glenoid fossa.
2. *Muscle forces* from muscle groups that flex, extend, and rotate the shoulder joint; only the deltoid muscle is modeled in this analysis.
3. *Intrinsic weight* of the arm.
4. *External forces* such as the weight of the ball in the hand.

It is also important to record the lines of action of the forces and moments in the free-body diagram. The point of application, direction (orientation), and magnitude of each force are included in the free-body diagram. The contact force is placed at the proximal end of the humerus; however, its direction (θ_j) and magnitude (F_j) are unknown.

The muscle force of the deltoid muscle is placed at its point of attachment to the humerus at a distance “a” from the glenohumeral joint center. The magnitude of the muscle force (F_M) is unknown. Lines of action of muscle forces (θ_M) are assumed on the basis of detailed anatomic dissections of joints. The force representing the weight of the arm (W_A) is assumed to be known and is placed at the center of mass of the arm at a distance “b” from the joint center. The force representing the arm weight is in the direction of gravity. The same is true for the ball of known weight held in the hand (W_B and distance “c”). The unknown variables are the magnitude of the contact force (F_j), the direction of the contact force (θ_j), and the magnitude of the muscle force (F_M). These variables are calculated using static force analysis.

A body is considered to be in static equilibrium when all forces and all moments acting on the body sum to zero. The summation of forces and moments may be performed around any point on the free-body diagram. For this two-dimensional model, the static equilibrium vector equations may be written in terms of their individual x, y, and z components:

$$\Sigma F_x = 0, \Sigma F_y = 0$$

and

$$\Sigma M_z = 0$$

When the force equilibrium equations are applied to the free-body diagram in Fig. 9.1b, the result is the following:

$$\Sigma F_x = 0 \rightarrow F_j \cdot \cos(\theta_j) = F_M \cdot \cos(\theta_M)$$

$$\Sigma F_y = 0 \rightarrow F_j \cdot \sin(\theta_j) = F_M \cdot \sin(\theta_M) - W_A - W_B$$

In a static analysis, the sum of moments (ΣM_z) may be taken at any coordinate location. In the current analysis, the sum of moments was taken about the point of application of the contact force on the humerus. The sum of moments was taken at this point to preclude the presence of the articulating surface contact force in the moment equation, yielding:

Fig. 9.1 (a) Person holding a ball in the hand at 90 degrees of shoulder abduction. Relative positions of bones in arm are indicated. (b) Free-body diagram of arm in 90 degrees of shoulder abduction (humerus, radius, and ulna are grouped together for simplification of analysis). a , b , c , distances from the glenohumeral joint center to forces acting on the limb; F_J , joint contact force; F_M , deltoid muscle force; θ_J , angle of joint contact force; θ_M , angle of deltoid muscle force; W_A , weight of arm; W_B , weight of ball.

$$\sum M_z = 0 \rightarrow F_M \cdot \sin(\theta_M) \cdot a = W_A \cdot b + W_B \cdot c = 0$$

The preceding equations are then solved to obtain the following:

$$F_M = (W_A \cdot b + W_B \cdot c) / (\sin(\theta_M) \cdot a)$$

$$\theta_J = \tan^{-1}((F_M \cdot \sin(\theta_M) - W_A - W_B) / F_M \cdot \cos(\theta_M))$$

$$F_J = \sqrt{(F_M \cdot \cos(\theta_M))^2 + (F_M \cdot \sin(\theta_M) - W_A - W_B)^2}$$

We now substitute values for the known variables $a = 15$ cm, $b = 30$ cm, $c = 60$ cm, $\theta_M = 15$ degrees, $W_A = 40$ N, and $W_B = 60$ N to solve for the unknown variables F_M , θ_J , and F_J . The calculated values are $F_M = 1236.4$ N, $F_J = 1214.3$ N, and $\theta_J = 10.4$ degrees.

This simple analysis shows a characteristic common to diarthrodial joints throughout the human body: poor mechanical advantage. The poor mechanical advantage of the shoulder is shown when the weight of the ball in the hand is compared with the muscle force required to maintain the ball position. The calculated muscle force is more than 20 times the weight of the ball! Altering two factors of the analysis may increase the mechanical advantage of the system by decreasing the muscle force required to hold the ball. First, an increase of θ_M would increase the component of F_M that resists the downward force of the weight of the arm and the weight of the ball. Another alternative would be to increase the moment arm of F_M , distance “ a ,” but this is often not practical. Second, we can flex the elbow and bring the weight of the arm and the weight of the ball closer to the center of rotation of the shoulder. This would change the resulting value from our moment equation and reduce our effective muscle force and resulting contact force.

A number of limitations to the static analysis exist due to the number of unknown variables. The number of static equilibrium equations available for use prevented the inclusion of additional muscle or ligamentous forces. That is, for a two-dimensional problem we could only use two force equations ($\sum F_x = 0$, $\sum F_y = 0$) and one moment equation ($\sum M_z = 0$) to solve the unknown variables. Stated differently, only three unknown variables may be determined in a two-dimensional analysis. If the analysis were performed in three dimensions, it would be possible to solve nine unknown variables. Owing to complex human anatomy and numerous muscle forces, we often have a greater number of unknown variables to solve than we have equations to use in the analysis. This results in an indeterminate problem.

Fig. 9.2 Fluid film lubrication. During motion at sufficiently high velocities, the weight tilts and forms a wedge shape. Because of the viscous properties of the fluid, a pressure will be created within the fluid to support the weight.

Several computational methods have been developed to increase the number of variables that may be solved. One is the exclusion of selected forces. For example, in the previous analysis, the teres minor muscle, an adducting muscle of the shoulder, was excluded because the shoulder was in pure abduction. A second is to reduce the number of unknown forces by assuming a force relationship between the different muscle units. For example, the supraspinatus muscle is also active during shoulder abduction, but it was excluded to limit the number of unknown variables. We may have assumed a relationship between the deltoid and supraspinatus, such as $F_2 = A \cdot F_1$, where F_2 is the muscle force of the supraspinatus, F_1 is the muscle force of the deltoid, and A is a constant. The relationship between different muscular units not included in the analysis may be formatted in a linear or nonlinear manner.

A third method to decrease the number of unknown variables would be to incorporate direct muscle electromyographic measurements into the analysis. A fourth method to increase the number of unknown variables is to use numerical optimization. Optimization is performed by minimizing a mathematical function that is defined as the “cost” of performing an activity of daily living. Various cost functions that have been used include minimization of muscular forces, muscle stress, and muscle energy. These cost functions have been successful in evaluating muscle forces during various activities of daily living. More advanced methods of optimization have incorporated muscle architecture to predict muscular forces accurately during activities of daily living.

Joint lubrication

The human joints are exposed to great variation in loading conditions. There can be high-impact, short-duration loads such as in running; moderately low loads with a prolonged loading time such as in standing; and low loads with rapid motion in the swing phase of walking. Over a lifetime there is relatively little wear in the joints, which indicates a highly effective lubricating system.

Two types of lubrication exist: boundary lubrication and fluid film lubrication. Boundary lubrication is due to a single layer (monolayer) of lubricant adsorbed on each bearing surface. In the case of a joint, boundary lubrication is achieved by a macromolecular monolayer attached to each articular surface. These layers carry loads and are effective in reducing friction. Fluid film lubrication is due to a thin film of lubricant and produces a greater bearing-surface separation. The pressure developed in the lubricating fluid carries the loads applied to the joint (Fig. 9.2).

The lubricating characteristics depend on the lubricant properties, such as viscosity, and on the shape of the gap between the two bearing surfaces and the relative velocity of the surfaces. In a human joint, the bearing materials, such as the articular cartilage, are not rigid and stiff. This results in what is known as *elastohydrodynamic lubrication*. As the joint surfaces move and pressure is developed, the fluid pressure deforms the surfaces (Fig. 9.3). This changes the film geometry by increasing the surface area, reducing escape of the lubricant from between the bearing surfaces and generating a longer-lasting film. These factors produce a lower stress within the joint.

In diarthrodial joints, a mixed mode of lubrication occurs, with the joint surface loads being sustained by fluid film pressures in areas of noncontact and by boundary lubrication in areas of contact (Fig. 9.4). In addition, cartilaginous joint surfaces differ from typical engineering bearings in that the cartilage is filled with fluid and is porous and permeable so that the surfaces can exude a lubricating fluid. As the joint moves and the surfaces

slide, fluid is exuded in front of and beneath the leading half of the load. Once the peak stresses decrease, fluid is reabsorbed back into the cartilage, and it returns to its original dimensions.

The viscosity of a lubricating fluid is important. Synovial fluid undergoes large changes in viscosity with changes in both temperature and velocity gradient. For very low velocities, a thinner lubricating film is desirable. Because synovial fluid is thixotropic, which means it can become fluid when agitated and then settle when left at rest, it can meet these requirements.

If a joint effusion is present, the velocity-dependent properties of the synovial fluid may be lost, which results in reduced lubrication and subsequent wear of the joint surfaces.

BIOMECHANICS OF TISSUES

Understanding how tissues respond to applied loads and deformation often provides insight into the progression of various rheumatic diseases. When

a force is applied to a tissue, the tissue will deform in response to the applied load. If a displacement is applied to the tissue, the tissue will produce a resistive force as a reaction to the applied displacement. Different loading modes exist throughout joints and tissues in the body (Fig. 9.5), often in combination. The amount of resulting deformation or reaction force produced by the tissue is directly related to the material composition, size, and shape of the tissue.

Structural properties versus material properties

Tissues can be tested as isolated individual samples (mechanical testing) or in an entire structural complex (structural testing). The structural properties of a tissue incorporate not only the material composition of the tissue but also its geometric configuration and mechanical environment.¹ Output from structural testing is shown as a force–displacement curve (Fig. 9.6). The units of force are newtons (N) or pounds force (lbf) and the units of displacement are typically millimeters (mm). Stiffness is a structural property of a body and is calculated as the slope of the elastic region of the force–displacement curve.

On the other hand, material properties of a tissue encompass the inherent material (chemical and physical) composition of the tissue itself (e.g., contribution of collagen fibrils in a tendon).¹ Output from mechanical testing is shown as a stress–strain curve. The units of stress are typically pascals (Pa, N/m²), whereas strain has no assigned units. The mechanical property of modulus is calculated from the stress–strain curve. Stress and strain are considered normalized values of load and displacement, respectively, on the

Fig. 9.3 Load carrying by lubricated bearings. A comparison of hydrodynamic lubrication (1) and squeeze film lubrication (2) of rigid surfaces, and elastohydrodynamic lubrication of deformable bearing surfaces under a hydrodynamic (sliding) action (3) and a squeeze film action (4). Surface deformation of elastohydrodynamically lubricated bearings increases the contact area, thus increasing the load-carrying capacity of these bearings.

Fig. 9.4 Mixed lubrication operates in articular cartilage: boundary lubrication in which the fluid film is as thick as the roughness of the bearing surfaces, and fluid film lubrication in which surfaces are more widely separated.

Fig. 9.5 Schematic representation of various loading modes.

basis of the geometry of the sample being tested (Fig. 9.7). Stress (σ) is calculated as the applied force divided by the initial cross-sectional area of the tissue sample: $\sigma = F/A_0$. Strain (ϵ) is calculated as change of length of the tissue sample divided by the initial length of the sample: $\epsilon = \Delta L/L_0$. Stress and strain and force and displacement may be positive or negative values. Additional information about the tissue may be extracted from the stress-strain curve (Fig. 9.8). For example, ductility is a measure of the amount of plastic deformation of a sample when it reaches failure, and resilience is the ability of a material to absorb energy when deformed elastically and to release the energy when unloaded.

Stress and strain

The stress distribution in a body is a quantitative description of the distribution of external forces acting through the body (Fig. 9.9). In three

dimensions, six independent stress components are required to describe the state of stress at each point in a body. Three of the stress components are normal stresses (tension-compression), and three stress components are shear stresses.

When an external force acts on the body, the body deforms to resist the applied load; this deformation is called *strain* (Fig. 9.10). In three dimensions, six independent strain components are required to describe the state of strain at each point in a body. Three of the strain components represent longitudinal elongation or compression of the body along the x, y, and z axes of the local coordinate system. The remaining three strain components represent the change of angles between the x-y axes, y-z axes, and z-x axes of the local coordinate system of the body.

We must assume a stress-strain relationship to calculate the stress within a tissue on the basis of experimental strain measurements. The stress in a body is related to the strain by the modulus of the body's material. This

Fig. 9.6 Force-displacement curve for a structure composed of a pliable material. If a load is applied within the elastic region (A-B) and removed, no permanent deformation occurs. If loading continues past the yield point (B) and into the plastic region (B-D) and is then released, permanent deformation results. The amount of permanent deformation that occurs if the structure is loaded to point C in the plastic region and then unloaded is represented by the distance between A and E. Structural stiffness is calculated as the slope of the linear portion of the elastic region.

Fig. 9.8 Ductility is a measure of the amount of plastic deformation at failure and is shown in this figure. Resilience is the ability of a material to absorb energy when deformed elastically and to release the energy when unloaded. Resilience is calculated as the area under the stress-strain curve line. The presence of shear strain in a structure loaded in tension and in compression is indicated by angular deformation.

Fig. 9.7 Different continuous structures composed of the same pliable material but with different geometries are tested. When individual forces are converted to stress and displacements are converted to strains, all loading curves are superimposed onto one another.

Fig. 9.9 Stress distribution within a material with tensile loading, compressive loading, and shear loading.

relationship may be complex and may consist of numerous modulus values. The exact number of modulus values depends on the homogeneity and isotropy of the test sample.² If a tissue is homogeneous, the mechanical properties of the tissue do not differ depending on the source location of the tested tissue sample. If a tissue is isotropic, the mechanical properties of the tissue do not change as the orientation of the tissue sample is changed. Most tissues in the body are inhomogeneous and anisotropic. Stress-strain plots of tissue samples from an inhomogeneous and anisotropic tissue (cartilage) are shown in Fig. 9.11.

The orientation and source location of the tissue sample significantly influence the stiffness of the tissue. Cartilage samples that are aligned with the preferred direction of collagen fibrils are stiffer than samples that are oriented perpendicular to the preferred direction. In addition, tissue samples from the articular surface are stiffer than tissue samples from deep within the tissue. Researchers often assume a tissue to be homogeneous and isotropic. This results in a requirement for only two variables to fully describe the force-displacement response of a tissue to mechanical loading: Young's modulus (E_y) and Poisson's ratio (ν). In one dimension, Young's modulus is calculated as the slope of the linear portion of the stress-strain curve. Poisson's ratio relates the longitudinal elongation (ϵ_y) of the material to the

Fig. 9.11 (a) Schematic diagram of collagen fiber orientation through the depth of articular cartilage. Superficial fibers are tangent to the articular surface. Fibers in the middle zone have no preferred orientation. Fibers in the deep zone are oriented radially to the subchondral surface. (b) Stress-strain diagram of cartilage testing in tension. Tissue sample A is from the same region as tissue sample B but is oriented 90 degrees to tissue sample B. Tissue sample C is from the same region as tissue sample D but is oriented 90 degrees to tissue sample D. Differences in stress-strain response indicate the anisotropic and inhomogeneous material nature of cartilage.

lateral contraction (ϵ_x) of the material (Fig. 9.12). Furthermore, soft tissues in the body have an evident viscoelastic component.

Viscoelasticity

For a viscoelastic tissue, the stress-strain response depends not only on the magnitude of the applied stress or strain, but also on the rate of the applied stress or strain. Viscoelastic tissues have three characteristic stress-strain responses: creep, stress-relaxation, and hysteresis. Creep is the deformational response of a tissue sample under a constant load (Fig. 9.13). Stress-relaxation is the stress response of a tissue sample under a constant displacement (Fig. 9.14). Hysteresis is the difference in path between loading and unloading of the tissue sample on a stress-strain diagram (Fig. 9.15). These responses can be shown diagrammatically on a ligament sample. We assume a ligament has been removed from a joint as a

Fig. 9.12 Poisson's ratio relates the longitudinal elongation of the material to the lateral contraction of the material. In an ideal incompressible material $v = 0.5$.

Fig. 9.13 In creep testing, an instantaneous stress (ϵ_o) is applied to a tissue sample at time t_o and maintained while the resulting tissue strain is recorded. Solid-like materials will exhibit an equilibrium deformation in response to the applied load, whereas fluid-like materials will elongate continuously.

bone-ligament-bone (BLB) segment. One end of the BLB has been anchored to the testing system through a load cell to measure applied force, and the other end of the BLB has been attached to the moveable cross-head of the testing system.

In a creep test, an instantaneous step or ramp load is applied to the tissue sample and held constant for an extended period of time (see Fig. 9.13). This is considered a load control test, and the resulting tissue displacement is measured. The displacement shows an initial elastic response of the tissue

Fig. 9.14 In stress-relaxation testing, an instantaneous deformation (σ_o) is applied to a tissue sample at time t_o and maintained while the resulting tissue stress is recorded. Tissues in the body have a solid component that will resist the applied deformation after interstitial fluid has been exuded from the tissue.

Fig. 9.15 The loading portion of the hysteresis curve (A) is always above the unloading portion of the curve (B). The area between the loading and unloading portions of the curve indicates relaxation of the collagen fibers within the ligament and the exuding of fluid from the ligament.

followed by a gradual increase of lengthening of the tissue. As the test proceeds, fluid is exuded from the tissue, and the solid components of the tissue are supporting the applied load. A "solid-like" material will be distracted to a point at which the solid components of the tissue will balance the applied load and will not elongate further. The modulus of the tissue is calculated as the stress of the tissue divided by the end displacement of the tissue. A

“fluid-like” material will not be able to balance the applied load and will continue to elongate.

In a stress–relaxation test, an instantaneous step or ramp displacement is applied to the tissue sample and held constant for an extended period of time (see Fig. 9.14). This is considered a displacement control test; the resulting tissue force is measured. An initial increase in force measured by the load cell is followed by a gradual reduction in force. The force eventually approaches an equilibrium value. The magnitude of the equilibrium value depends on the solid or fluid nature of the tissue. A solid-like material will have a final stress that is not zero. A fluid-like material will have a final stress that is close to or equal to zero.

Finally, hysteresis of a soft tissue is displayed while the tissue is cycled to a known force or displacement and back to its initial position (see Fig. 9.15). As shown in the figure, the loading portion of the force–displacement curve is always higher than the unloading portion of the curve. The area

between the loading and unloading curves represents nonrecoverable energy that is lost during testing.

The viscoelastic responses of the ligament are due to the interaction of fluid and solid components of the ligament: water and collagen, respectively. In a relaxed state before loading, the ligament is approximately 60% to 80% water and contains collagen bundles that have a wavy appearance. When a force or displacement is applied to the ligament, the fluid is exuded through pores in the tissue and the collagen fibers begin to straighten. In a creep test, a majority of the fluid is exuded from the tissue and the applied load is balanced by the straightened collagen bundles. In a stress–relaxation test, the collagen bundles are straightened by the imposed displacement and fluid is initially exuded in response to the rapid increase in interstitial fluid pressure. As time passes, the interstitial fluid pressure comes to equilibrium and fluid is no longer exuded. A combination of the fluid-solid effects is seen in a hysteresis loop.

Biomechanics of the spine

■ MICHAEL A. ADAMS ■ PATRICIA DOLAN

- Genes and the environment contribute approximately equally to the strength of spinal tissues.
- Moderate mechanical loading strengthens vertebrae and (eventually) intervertebral disks.
- Muscle forces on the spine usually exceed gravitational forces, and inertial forces arising during accelerations and falls are often the greatest of all.
- Intervertebral disks and vertebral bodies resist spinal compression, with the fluid properties of the disk nucleus spreading compressive load evenly on the vertebral bodies in all postures.
- Neural arches protect the intervertebral disks (and spinal cord) from shear, torsion, and bending.
- The intervertebral ligaments limit spinal bending, but most are slack in upright postures so that the spine can move freely within its “neutral zone.”
- Compressive overload damages the vertebral body, decompresses the adjacent disk, and can lead to internal disk disruption.
- Combined loading in bending and compression can create radial fissures in the disk anulus and cause disk prolapse, even in macroscopically normal disks.
- Injury to the disk anulus or endplate alters the mechanical environment of disk cells and thereby creates a vicious circle of matrix weakening, reinjury, and frustrated healing.
- Loss of anulus height can initiate a “degenerative cascade” involving segmental instability, vertebral osteophytosis, and apophyseal joint osteoarthritis.
- In elderly people, vertebral strength decreases with decreases in activity and hormone levels, and patterns of vertebral deformity also depend on disk degeneration.

INTRODUCTION

Relevance of biomechanics

Spinal pain and deformity often arise from degenerative conditions that depend on age and genetic inheritance, and all aspects of human behavior (including responses to pain and to treatment) are strongly influenced by psychosocial factors. Consequently, the old *injury model* of back pain has been replaced by the *biopsychosocial model*,¹ which recognizes all these diverse influences. This does not mean, however, that biomechanics can be disregarded. Mechanical loading can make spinal tissues stronger or initiate degenerative changes within them, and genes influence mechanical characteristics as much as biologic ones.

Genes versus environment

Studies on human twins can reveal the “heritability” of a specific disease, expressed as the percentage of the disease variance that is associated with genetic inheritance. Early studies of intervertebral disk degeneration, vertebral fracture, back pain, and neck pain reported heritability values in excess

of 70%, but most current estimates are closer to 50%.²⁻⁴ The finding that heritability of disk degeneration falls to 30% in the lower lumbar spine, where mechanical loading is most severe, highlights the complementary role of environmental influences.⁴ It appears that genes and the environment contribute in approximately equal measure to the most common manifestations of spinal pathology and pain, and of the environmental influences, mechanical loading is the best documented and most easily modified. Also, of course, the genetic component includes inherited influences on mechanical factors, such as body weight and muscle strength.

Adaptation versus injury

The old “injury model” supposed that all mechanical loading is harmful to the spine, even though repetitive mechanical loading is known to strengthen muscles and bones according to the principles of adaptive remodeling.⁵ Articular cartilage and intervertebral disks can also become mechanically conditioned given enough time.^{6,7} Evidently, it is not mechanical loading that should be avoided but mechanical *overload*, which physically disrupts tissues. Epidemiologic studies that fail to make this distinction underestimate the influence of mechanical overload on spinal health. So too do cross-sectional surveys that ignore the “healthy worker effect” whereby those with back pain move to less arduous occupations.⁸ From a biomechanics standpoint, moderate spinal loading should be encouraged, although the risk for injury should be minimized. In the words of Nietzsche, “What does not kill him makes him stronger!”

The purpose of this chapter is not to revive the “injury model” but to take a fresh look at biomechanical influences in spinal disorders, including intervertebral disk degeneration, osteoarthritis, osteoporosis, and whiplash.

FORCES ACTING ON THE SPINE

Compression, shear, bending, and torsion

Compressive forces on the spine act down its long axis, at right angles to the midplane of the intervertebral disks (Fig. 10.1). The curvature of the spine ensures that the direction of the compressive force varies between spinal levels, and this is consistent with the origins of this force, which is primarily tension in the paraspinal muscles. *Shear* acts at right angles to the compressive force and causes vertebrae to slide forward, backward, or sideways relative to adjacent vertebrae. *Bending* moments (measured as a force multiplied by a lever arm in units of Newton meters [Nm]) cause the spine to bend, usually relative to the center of rotation within each intervertebral disk. *Torsional* moments, or torques, have the same units as bending moment and cause the spine to twist about its long axis (axial rotation).

Gravitational forces

Gravity exerts a vertical force on each body segment: its weight. Superincumbent body weight ranges from 55% of whole-body weight at the fifth lumbar vertebral level to 7% at the first cervical level. These forces are generally only a small proportion of the total force acting on the spine during vigorous activity.

Inertial or dynamic forces

When a body segment is accelerated, the force acting on it is amplified according to Newton’s second law of motion: Force = mass × acceleration.

Fig. 10.1 The lumbar spine showing the directions of compressive (C) and shear (S) forces acting on the lumbosacral disk. Spinal compression acts perpendicular to the midplane of the disk, and thus its direction varies with the spinal level. A bending moment (BM) causes the spine to bend in flexion, extension, or lateral bending. Axial torque (AT) causes axial rotation about the long axis of the spine. (Reproduced with permission from Adams MA, Bogduk N, Burton K, Dolan P. *The biomechanics of back pain*. 3rd ed. Edinburgh: Churchill Livingstone; 2013.)

Exceptionally high acceleration occurs when the human body is ejected from an aircraft, and the compressive force on the lumbar spine can then be enough to cause vertebral fracture. More typically, the human spine is subjected to high deceleration during falls, especially when the impact velocity is high and the surface is so hard that velocity is brought to zero in a very short time.

Muscle forces

Tension in a contracting muscle compresses the bones that lie between the muscle's tendinous insertions. Muscle forces are hidden in the sense that they are internal to the body, but they often reach high levels for the reason illustrated in Figure 10.2. Essentially, muscles act on short internal lever arms and consequently must exert forces that are several times greater than the external loads that often act on much greater lever arms. Frequently, the external load is dominated by the weight of the upper part of the body, which is why lifting an object as small as a pen from the floor can generate a peak tensile force in the back muscles of greater than 200 kg.⁹ (Approximately 1 kg = 2.2 lb = 9.81 N.) The highest forces tend to arise when muscles accelerate or decelerate body segments, especially during eccentric (lengthening) contractions when the collagenous tissue within muscle is severely stretched. The need to stabilize the body in a moving environment often requires high levels of cocontraction of the paraspinal and abdominal muscles.

High muscle forces have a number of practical implications. In the medicolegal arena, many clinicians underestimate muscle forces by supposing (quite wrongly) that forces on the spine or neck must be low when the external loads are light. The potential danger of muscle contractions is

Fig. 10.2 During manual handling, high tensile force (F) must be created by the back muscles to generate an extensor moment (EM) large enough to lift up an external weight (W) and the weight of the upper part of the body (w). The back muscles act on a short internal lever arm (d) as opposed to the long lever arms (D, d_w) of the objects being lifted. In practice, muscle force F is often much greater than the weight being lifted, so the compressive force acting on the spine (C) rises to approximately 500 kg when a weight of 20 kg is lifted. (Reproduced with permission from Adams MA, Bogduk N, Burton K, Dolan P. *The biomechanics of back pain*. 3rd ed. Edinburgh: Churchill Livingstone; 2013.)

illustrated by the finding that epileptic fits can cause the back muscles to crush vertebrae, even when no falls are involved.¹⁰

Intraabdominal pressure

People struggling to lift a heavy weight usually hold their breath and go red in the face, thus indicating a common if unwitting strategy to stabilize the spine and protect it from high force. Contracting trunk muscles generate high pressure in the abdominal cavity, which can then transmit a compressive force directly from the thoracic spine and ribs to the pelvis and bypass the lumbar spine. The mechanism is difficult to quantify because tension in some abdominal muscles acts to compress the spine further. However, raising intraabdominal pressure would be most beneficial when the spine is flexed, when a thick belt is worn to provide lateral support to the abdomen, or when the pressure is raised primarily by contraction of the transversus abdominis, which does not compress the spine.¹¹

Diurnal variation

In the early morning, disks are swollen with water, so the anulus and intervertebral ligaments resist bending strongly and are most vulnerable to injury.¹¹ As the day progresses, disks lose 20% of their water and height, so the spine becomes more supple, but the neural arches then resist more of the compressive force on the spine. These diurnal changes explain why backache often increases after several hours of standing and why recurrent

Fig. 10.3 The compressive force acting on the lumbar spine increases to 2000 N (approximately 200 kg) with stooped, standing postures. Forces were calculated from pressure in the L4-5 intervertebral disk nucleus measured *in vivo* by a miniature pressure transducer. "Angle of motion segment" refers to the relative orientation of the upper and lower endplates of the L4-5 disk. (Reproduced with permission from Sato K, Kikuchi S, Yonezawa T. *In vivo* intradiscal pressure measurement in healthy individuals and in patients with ongoing back problems. *Spine* 1999;24:2468-74.)

back pain can be reduced by avoiding flexion movements during the early morning.¹²

Measurement of spinal loading *in vivo*

The total compressive force acting on the spine of a living volunteer can be measured by inserting a pressure-sensitive needle into an intervertebral disk. Hydrostatic pressure measured in the disk nucleus can then be converted to compressive force by calibrating the transducer in cadaveric spines. The compressive force on the L4-5 disk of healthy subjects (average body weight, 73 kg) ranges from 14 kg when lying prone to more than 200 kg in the stooped, standing position,¹³ as shown in Figure 10.3. Relaxed sitting increases disk compression more than standing does because sitting flexes the lower lumbar spine and generates additional tension in the posterior ligaments whereas a lordotic standing posture causes some of the compressive force to be resisted by the neural arch.¹⁴

Measurement of spinal loading *in vivo* can be difficult when the spine is moved forcefully because inserted pressure transducers cannot be used safely. During manual handling, spinal compression can be quantified from the electromyographic signal recorded from the skin surface of the back. The electromyogram can be calibrated against the moments and forces generated during isometric exertions and then used to calculate muscle forces on the spine during vigorous movements.⁹ Peak compressive forces on the lumbar spine vary between 250 and 500 kg when lifting objects weighing up to 30 kg from the floor. Rapid lifting increases peak loading by more than 60% when compared with slow lifting, and forces of this magnitude can cause fatigue ("wear-and-tear") damage to accumulate in some spines. Similar peak forces are reported when mathematic models are used to calculate spinal loading from optical measurements of the movement and acceleration of various body parts.¹⁵

Shear forces and torques have not been measured reliably *in vivo*, but mathematic models show that peak anterior shear forces reach 150 to 200 kg in the lower lumbar spine when heavy weights are lifted.¹⁵ Much of this force can be resisted by the back muscles.¹¹

The peak bending moments acting on the spine of a living person can be estimated by measuring the moment required to bend a cadaveric spine to the same angle. The technique has been used to show that bending moments on the lumbar spine rise to 10 to 25 Nm during heavy lifting.⁹ Cadaveric spines can be flexed more than this before they are damaged, so in life, back muscles must normally protect the spine from excessive flexion. However, protective muscle reflexes can be impaired if the spine is flexed repeatedly or for periods of an hour or more.¹⁶ This could explain why activities such as gardening and long-distance driving are often associated with back pain.

MECHANICAL FUNCTION OF THE SPINE

Spinal curvature

Cervical lordosis appears when infants first lift their heads up, and lumbar lordosis develops when walking begins. Thoracic kyphosis appears to be a compensatory mechanism to maintain a level line of sight and to increase the volume of the thoracic cavity. Spinal curves probably play a shock-absorbing role during locomotion because the natural tendency for the curves to flatten and accentuate as the body rises and falls is resisted by the muscles of the trunk. The tendons of these muscles have a great capacity to store strain energy (which is proportional to tendon tension multiplied by stretch) such that the tendons of paraspinal muscles are able to act as shock absorbers and minimize vertical accelerations of the head.¹¹ A similar mechanism allows the quadriceps tendons to absorb energy when the knees are flexed to soften the landing from a jump.

Spinal movements

Intervertebral movements in living people combine angular rotations with small gliding movements (*translations*) in the plane of the disk. Angular rotations involve stretching and compressing the disk anulus in such a manner that the center of rotation (the theoretical pivot point) moves around within the disk nucleus.¹¹ The oblique surfaces of the apophyseal and uncovertebral joints ensure that certain movements are mechanically "coupled"; for example, attempted lateral bending normally creates a small axial rotation as well. The cervical spine is the most mobile region because the cervical intervertebral disks are relatively thick in comparison to the height of adjacent vertebral bodies. Conversely, the thoracic spine is the least mobile because its disks are narrow and movements are inhibited by the ribs and dipping spinous processes. Mobility of the lumbar spine declines by approximately 50% between the ages of 16 and 85 years.¹¹ This is partly due to disk narrowing, which brings the neural arches of adjacent vertebrae closer together and causes the center of rotation for flexion and extension to migrate posteriorly toward the apophyseal joints.¹⁷

Intervertebral disk mechanics

The central nucleus pulposus of an intervertebral disk normally has such a high water content that it behaves like a pressurized fluid, with compressive load being spread evenly on the adjacent vertebral bodies¹³ even when the vertebrae are angled in flexion or extension. The layers (lamellae) of the anulus fibrosus act in tension to retain this pressurized nucleus, but the adult human anulus is sufficiently fibrous to resist direct compressive loading as well. The internal mechanical functioning of loaded cadaveric lumbar disks has been investigated by pulling a needle-mounted pressure transducer along their midsagittal diameter. The resulting "pressure profiles" (see later) show the extent of the fluid-like region and the pressure within it. Both decrease with age, whereas the compressive stress (force per unit area) resisted by the anulus increases.¹⁸ Cervical disks behave in essentially the same way.¹⁹

Spinal resistance to noninjurious loading

Compression

Compressive loading of the spine is resisted mostly by the disks and vertebral bodies. As the compression increases, the disk anulus bulges radially outward and the vertebral endplates bulge vertically into the vertebral bodies.²⁰ The relatively high stiffness of the intervertebral disks and vertebral endplates (in comparison to tendons, for example) ensures that they are not good shock absorbers. A small proportion of the compressive force is normally resisted by the neural arch; this rises to 20% after sustained loading of the disk and when the spine is bent backward slightly to simulate the upright standing posture.¹⁴

Shear

The apophyseal joints resist the forward shearing movements of adjacent vertebrae (see Fig. 10.1), with the more frontal plane orientation of the lower lumbar joints making them particularly well suited to prevent any forward slip of the overlying vertebra.

Torsion

Similarly, the articular surfaces of the apophyseal joints are well orientated to resist axial rotation. In the lumbar spine, only 1 to 2 degrees of rotation is permitted before the articular surfaces make firm contact, but considerably more movement is allowed in the thoracic and cervical spine.¹¹

Stretching of the apophyseal joint capsule and ligaments on the tension side and deformation of the disk annulus also contribute substantially to the spine's resistance to torsion. Loss of apophyseal joint articular cartilage after osteoarthritis can allow more free play in these joints and increased range of axial rotation. The unique shape of the first two cervical vertebrae allows a much greater range of axial rotation.

Bending

Ligaments of the neural arch initially reorient when the spine is flexed. They then resist the movement strongly, with the interspinous and supraspinous ligaments being the first structures to be damaged during hyperflexion. The strong capsular ligaments of the apophyseal joints resist flexion the most, followed by the disk.¹¹ The ligamentum flavum has such a high content of elastin that it can be stretched by up to 100% in full flexion, even though it is the only intervertebral ligament to be prestressed in the upright “neutral” position. The posterior longitudinal ligament is weaker than the annulus to which it adheres and therefore does not protect it effectively from hyperflexion. A plexus of the mixed (autonomic/sympathetic) sinuvertebral nerve lies in the posterior longitudinal ligament, thus suggesting that its primary function may be to serve as a “nerve net” for detection of abnormalities in the underlying disk.¹¹ Backward bending (spinal extension) is resisted by the bony surfaces of the neural arch, with most resistance coming from either the facet joints or the spinous processes, depending on individual variations in anatomy. The shape of most disks (wider from side to side than from front to back) suggests that they resist lateral bending strongly, together with the apophyseal joint on the side that is being compressed. In life, lateral bending is often combined with flexion when individuals bend awkwardly to pick something up that is not directly in front of them. Such bending movements permit extra stretching of one posterolateral corner of the disk (the most usual site of herniation) because the additional component of lateral bending is not resisted by the interspinous and supraspinous ligaments, which lie on the axis of lateral bending.

INJURY

Fracture of the vertebral body

Compressive overload invariably damages the vertebral body before the intervertebral disk, even if the inner annulus of the disk is artificially weakened.¹¹ In a young or middle-aged person, the vertebral endplate is the most common site of injury since it is fractured by high pressure in the nucleus of the adjacent disk. Cranial endplates (relative to the vertebra) are injured more often than caudal endplates because they are thinner and supported by less dense trabecular bone.²¹ If nuclear tissue is expressed into the vertebral body (Fig. 10.4a), it eventually becomes surrounded by a calcified layer known as a Schmorl node (Fig. 10.4b). Endplate lesions in general are associated with mechanical loading, disk degeneration, and back pain.²²

Spondylolysis and spondylolisthesis

Spondylolysis represents a fracture of the pars interarticularis and occurs either unilaterally or bilaterally in the lower lumbar spine. It can be reproduced in cadaveric spines by bending the neural arch backward relative to the rest of the vertebra or by simulating spinal flexion movements that cause the tension in ligaments and muscles to pull the neural arch forward and downward.¹¹ Alternating movements in extension and flexion therefore have the potential to bend the neural arch backward and then forward²³ and create stress reversals, which are problematic for bone metabolism. This could explain why spondylolysis is associated with sports such as cricket and gymnastics, which involve extreme flexion and extension. Adolescents are affected the most because the reduced mineralization in their vertebrae allows much greater angular movements at the pars.²³ The L5 disk is affected most because it joins the mobile spine to the relatively immobile sacrum and it often lies at a steep angle to the horizontal (see Fig. 10.1) such that gravity contributes to the forward shearing force.

Spondylolisthesis is forward slip of a vertebra. It often follows bilateral spondylolysis in adolescents, but not invariably, thus suggesting that strong back muscles can keep the vertebrae in place.

Apophyseal joint injury

These small synovial joints are most likely to be injured by excessive shear or torsional loading. They are particularly vulnerable to torsion, which concentrates compressive loading on only one of the two joints, and damage occurs at a torque of 10 to 30 Nm.¹¹ The inferior and superior margins of

Fig. 10.4 (a) Midsagittal section through a lumbar disk and vertebrae showing vertical herniation of the nucleus pulposus (arrow) as a result of compressive overload *in vitro*. In life, calcification around the herniation would create a Schmorl node. Note the inward collapse of the inner annulus (*). (b) Radiograph of a midsagittal section of a lumbar vertebra (anterior on the left). Note the large Schmorl node extending from the center of the upper endplate (arrow) and the large osteophytes on the anterior vertebral margins. (c) Compressive and bending overload *in vitro* can cause some nucleus pulposus (arrow) to herniate through a radial fissure in the posterior annulus (*). (Adapted from Adams MA, Bogduk N, Burton K, Dolan P. *The biomechanics of back pain*, 3rd ed. Edinburgh: Churchill Livingstone, 2013.)

the articular surfaces are most frequently affected by cartilage loss and by osteophytes,²⁴ which suggests that damage also occurs when the spine is heavily loaded in flexion or extension and when disk height is reduced. Hyperextension of the spine can cause the inferior articular processes to stretch and probably damage the apophyseal joint capsules.²³

Disk herniation

Cadaveric experiments have shown that apparently normal disks can be made to herniate (i.e., prolapse) posteriorly by loading them simultaneously in bending and compression.²⁵ A single application of severe loading can cause extrusion of the nucleus pulposus (see Fig. 10.4c), and the disks most readily affected are the lower lumbar disks in those aged 30 to 50 years. In these experiments, either the bending or the compression had to exceed normal limits, but not both. More moderate but repetitive loading of disks in those aged 20 to 40 years can create radial fissures that allow nuclear material to migrate posteriorly but without permitting bulk extrusion of the nucleus from the disk space.¹¹ The underlying mechanism, which is explained by mathematic models,²⁶ is that spinal bending stretches and thins the opposite wall of the annulus so that the annulus rather than the vertebral endplate fails first when compressive loading increases nuclear pressure. If a radiopaque gel is forcibly injected into the nucleus, it can insinuate itself into and between the lamellae of the annulus,²⁷ thus suggesting that compressive loading alone might create a radial fissure in a human disk over a time scale of weeks or years rather than hours.

Herniated nuclear material swells by 200% to 300% in just a few hours before shrinking again over a period of several days as it loses proteoglycans.¹¹ This transient phenomenon could explain why sciatica sometimes develops gradually after a back injury.

Internal disk disruption

Internal disruption of the lamellar structure of the annulus is more common than disk prolapse. Circumferential or radial fissures may develop in the annulus (see Fig. 10.4c), or it may collapse into the nuclear cavity (see Fig. 10.4a). Internal disruption can be caused *in vitro* by traumatic or repetitive

Fig. 10.5 (a) Photograph showing a mature nondegenerated human intervertebral disk cut through in the midsagittal plane. The graph below it shows how the horizontal and vertical components of compressive stress vary within such a disk. There is a central region of hydrostatic pressure (the “functional nucleus”) and a small concentration of compressive stress in the posterior annulus. (b) Internal disruption of the annulus lamellae and the damaged endplate indicate that this young adult disk is degenerated. Stress distributions in such a disk show a decompressed nucleus and high stress concentrations (arrows) in the annulus. The generally low disk stress suggests that some compression has been transferred to the neural arch. Approximately 1 MPa = 10 kg/cm². (Adapted from Adams MA, Bogduk N, Burton K, Dolan P. *The biomechanics of back pain*. 3rd ed. Edinburgh: Churchill Livingstone; 2013.)

loading involving bending and compression.²⁵ The simplest method is to damage the weak vertebral body endplate, which allows the pressurized nucleus to expand vertically, thereby reducing the pressure within it (Fig. 10.5) and allowing inward collapse of the inner annulus (see Figs. 10.4a and 10.5b). This mechanism has been demonstrated in cadavers²⁵ and confirmed in live animals.²⁸

Ligament injuries

Excessive flexion tears the interspinous and supraspinous ligaments, followed by the capsular ligaments of the apophyseal joints. Extreme hyperflexion is required to tear the posterior wall of the disk or the ligamentum flavum, typically at a bending moment of 60 Nm.¹¹ In extension, injury may occur at 35 Nm. Equivalent values for the cervical spine are 7 and 8 Nm, respectively. The elastic limit probably marks the end of the physiologic range of motion, at which point a clinically relevant injury would be sustained in life. Little is known about injuries to the iliolumbar ligaments or their role in back pain.

Whiplash

The essential feature of whiplash is a painful bending injury to the neck that is caused by a low-velocity insult, such as a car “shunt.” Low velocity does not mean that low force is involved. Laboratory simulations on cadavers²⁹ and live volunteers³⁰ show that a rear impact thrusts the shoulders forward relative to the head such that the neck is initially distorted into an “S” shape, involving hyperextension of the lower cervical levels and variable flexion and extension of the upper cervical levels (Fig. 10.6). This initial distortion is followed by general hyperextension. Finally, depending on the nature of the impact and the position of the headrest, the neck can be thrown into hyperflexion. The key feature of whiplash is that significant movements occur in less than 50 msec, before the neck muscles can resist them. Consequently, the head is thrown around relative to the slender neck

Fig. 10.6 During a rear-impact whiplash injury the neck adopts an S-shaped deformity after only 50 msec, before it can be protected by muscle action. Subsequently, the neck is thrown into hyperextension and possibly also into hyperflexion. (Reproduced with permission from Adams MA, Bogduk N, Burton K, Dolan P. *The biomechanics of back pain*. 3rd ed. Edinburgh: Churchill Livingstone; 2013.)

like a “balloon on a stick.” The cervical spine has approximately 45% of the compressive strength of the lumbar spine but only 20% of its strength in bending,³¹ which suggests that the neck is particularly vulnerable to bending injury.

The frequent involvement of both flexion and extension ensures that practically any structure in or around the cervical spine can be injured

during whiplash.³² The site of injury would move away from the sagittal midline (perhaps to an apophyseal joint) if the victim was turning his head around at the time of impact. Any previous warning would allow the victim to contract the neck muscles in alarm, thereby causing a higher proportion of compression to bending to act on the cervical spine and possibly increasing the risk for injury to muscles and intervertebral disks. As with any other human behavior, reports of symptoms persisting after whiplash are subject to a variety of psychosocial influences.³²

BIOMECHANICS OF DISK DEGENERATION

Middle-aged disks are vulnerable to injury

Loss of proteoglycans and water from aging intervertebral disks is confined mostly to the nucleus, where it leads to a smaller hydrostatic region exhibiting lower pressure. Consequently, high concentrations of compressive stress (force per unit area) develop within the annulus, particularly posterior to the nucleus.¹⁸ Aging annulus tissue is stiffened by increased collagen cross-linking, especially the nonenzymatic glycation reactions that are known to stiffen articular cartilage and render it more vulnerable to injury.³³ The accumulation of small defects in the annulus ensures that its strength does not increase with stiffness; in fact, strength can fall slightly.⁷ The vertebral endplates and their supporting trabeculae also weaken with age, in common with most bone structures, and endplates develop increasing concavity on the disk side. This further reduces nucleus pressure and concentrates stress in the annulus. Hence, increasing stress concentrations, increasing stiffness, and accumulating structural defects make middle-aged disks vulnerable to injury. The risk for injury appears to decrease in old age, possibly because older people are less active and because sarcopenia reduces the peak forces that can be generated by aging back muscles.³⁴

Injury alters matrix stress

As described earlier, severe loading in bending and compression can create radial fissures in the annulus and allow disk herniation, whereas excessive compressive loading can damage the endplate and lead to internal disruption. Either way, the annulus loses height and bulges radially like a “flat tire.”²⁰ Within the disk, the distribution of compressive stress often becomes highly irregular, as shown in Figure 10.5b.

Injury, degeneration, and “frustrated healing”

Disk cells respond to moderate fluctuating hydrostatic pressure by synthesizing more proteoglycans, and they respond to extreme or static pressure by synthesizing less.³⁵ The altered stress distributions in injured disks should therefore inhibit proteoglycan synthesis and lead to reduced nuclear hydration and pressure, which is the reverse of what would be required to reinflate the injured disk. This then provides a mechanism for progressive disk degeneration: injury affects the mechanical environment of disk cells in such a manner that their metabolism becomes aberrant, thereby leading to further weakening of the matrix and reinjury.³⁶ The mechanism is supported by evidence from animal experiments²⁸ and organ culture.³⁷ Attempts by the disk to heal itself are frustrated by metabolite transport problems, which limit disk cell density³⁸ and hence tissue turnover. However, metabolite transport through the endplate increases with age and degeneration,³⁹ so it is unlikely to be a primary cause of disk degeneration.

Discogenic pain

Intervertebral disks become avascular at about the time that a child learns to stand upright, presumably because the high hydrostatic pressure within the tissue collapses any blood vessels. Conversely, any loss of pressure in an injured or decompressed disk would allow blood vessels and nerves to grow back in again, as reported in severely degenerated and painful disks.⁴⁰ Ingrowth will be facilitated by focal loss of proteoglycans and reduced mechanical pressure within annulus fissures,⁴¹ and by structural damage to the endplate. There is no longer any doubt that disk degeneration is associated with an increased risk for back pain,⁴² and mechanical factors contribute directly to that pain, as well as to the underlying degeneration.

Disk prolapse

As degeneration progresses, internal disruption and radial fissures typically reduce disk height by 3% per year⁴³ and allow the nucleus pulposus to

approach the disk periphery. Excessive loading can precipitate herniation at any stage, and the fact that prior degeneration is not essential for prolapse to occur (see Fig. 10.4c) is an important medicolegal consideration.¹¹

SPINAL DEGENERATIVE CASCADE

Intervertebral disks play such an important role in spinal mechanics that disk failure initiates a whole cascade of adverse changes in adjacent tissues.

Segmental instability

Loss of nuclear pressure and volume removes tension from the surrounding annulus, and loss of disk height creates slack in the intervertebral ligaments. These mechanical changes are sufficient to create “segmental instability” in the motion segment, as manifested by reduced resistance to bending and an increase in horizontal shearing movements.¹⁷ In effect, the segment “wobbles” and has an increased region of free play (or “neutral zone”). The situation is more serious if the endplate becomes damaged because this causes immediate and gross decompression of the nucleus, as shown in Figure 10.5a. Segmental instability is associated with back pain, although the supporting evidence is slight. Pain could arise from the stress concentrations in the annulus (and apophyseal joints) that accompany nuclear decompression rather than from the small movements themselves. Instability should not be confused with hypermobility, which is a systemic condition involving increased ranges of movement.

Vertebral body osteophytes

Segmental instability is probably a transient phenomenon because it can be corrected by the growth of osteophytes on the margins of the vertebral bodies (see Fig. 10.4b) adjacent to the “wobbling” disk. Osteophytes can be created by an injury to the annulus⁴⁴ and grow in parallel with disk narrowing,⁴³ presumably because increased bulging of the annulus pulls on the periosteum. The primary mechanical effect of vertebral body osteophytes is to increase the disk’s resistance to bending,⁴⁵ hence reversing the initial destabilizing influence of disk degeneration. In this light, osteophytes can be viewed as adaptive rather than degenerative.

Apophyseal joint osteoarthritis

Loss of height because of a degenerated annulus brings the adjacent neural arches closer together so that they resist up to 90% of the compressive force acting on the lumbar spine rather than the normal 0% to 20%.¹⁴ Abnormal load-bearing creates high concentrations of compressive stress in the inferior margins of the joint, especially in habitual upright postures.⁴⁶ In addition, direct bone-on-bone contact between the inferior articular processes and the laminae below can lead to gross bone remodeling, including osteophytes. A close relationship between high load-bearing and osteoarthritic changes, including cartilage loss, bone eburnation, and sclerosis, has been noted in cadaveric apophyseal joints.⁴⁷ Imaging studies *in vivo* have long suggested such a relationship.

Spinal stenosis

The height of the intervertebral foramen is decreased by narrowing of the annulus fibrosus. Its anteroposterior diameter is also decreased as a result of radial bulging of the disk and by osteophytosis of the apophyseal joint. These changes can combine to cause a severe reduction in the cross-sectional area of the foramen and subsequent trapping of the exiting nerve. The consequences of spinal stenosis are usually most severe at L5-S1, which has a particularly small foramen.

Degenerative scoliosis

The two apophyseal joints at each spinal level often show pronounced left-right asymmetry, a condition known as *tropism*. If the affected joints become heavily load bearing as a result of disk narrowing (see earlier), their oblique articular surfaces will create an unbalanced torque about the long axis of the spine that leads to axial rotation. Axial rotation is mechanically “coupled” to lateral bending and can also be coupled to flexion and extension, so a “triplanar” spinal deformity develops that involves permanent twisting, lateral bending, and flexion of the thoracolumbar spine. This is a plausible explanation for degenerative scoliosis, but the mechanism has not been proved.

OSTEOPOROTIC VERTEBRAL DEFORMITY

Reduced loading weakens old vertebrae

When a vertebral body is loaded naturally by adjacent intervertebral disks, its compressive strength depends primarily on its size and bone mineral density (BMD).⁴⁸ Old vertebrae lose BMD and strength, partly as a result of hormonal changes and partly because muscle strength decreases with age³⁴ and thus provides a reduced mechanical stimulus to maintain bone mass.⁴⁹ Hormone levels and muscle strength are themselves influenced by genetic inheritance, as well as by environmental factors.

Mechanisms of deformity

The nucleus and inner annulus of a nondegenerated disk press evenly on adjacent vertebral bodies (see Fig. 10.5a), even when the spine is flexed or extended. If BMD falls, nuclear pressure can drive the central region of the adjacent vertebral endplates outward and create “biconcave” deformities in the vertebrae. Degenerated disks, on the other hand, concentrate compressive stress on the anterior and posterior vertebral body margins (see Fig. 10.5b) in flexion and extension, respectively. If the disk is also grossly narrowed, the neural arch resists much of the compressive load on its own, especially in upright postures.¹⁴ In many elderly spines, these factors combine to “stress-shield” the anterior vertebral body in upright postures, which causes it to lose BMD (Fig. 10.7). Unfortunately, flexion movements can then disengage the neural arches and transfer high compressive stress onto the weakened anterior vertebral body,⁵⁰ thereby creating anterior wedge deformities and senile kyphosis. (It is sometimes assumed that kyphotic posture is a cause of anterior wedge deformity rather than a consequence, but this is mistaken; if increased habitual loading of the anterior vertebral body was threatening it with collapse, this region of bone would have an elevated BMD rather than the reduced BMD commonly seen.) The third type of vertebral deformity, a “crush fracture,” probably results from high compressive impacts when the disks are degenerated.

Fig. 10.7 (Left) The three percentages show how an applied compressive force is distributed between the anterior half of the vertebral body and disk, the posterior half of the vertebral body and disk, and the neural arch (average data for cadaveric specimens with severely degenerated disks tested in the simulated erect standing posture). (Right) Plain radiograph of such a specimen showing how image intensity (which reflects bone mineral density) is very low anteriorly and very high in the apophyseal joints. (Image and data adapted from Adams MA, Pollintine P, Tobias JH, et al. Intervertebral disc degeneration can predispose to anterior vertebral fractures in the thoracolumbar spine. *J Bone Miner Res* 2006;21:1409-16.)

Principles of genetic epidemiology

■ JANE WORTHINGTON ■ STEVE EYRE

- The majority of rheumatic conditions have a complex etiology in which multiple genetic and environmental effects interact to cause disease.
- Many rheumatic diseases are associated with HLA class II or class I locus alleles, thus suggesting an immune-mediated component in these conditions.
- Genome-wide association studies using hundreds of thousands of single nucleotide polymorphisms genotyped in large samples of cases and controls have successfully identified large numbers of susceptibility loci for the rheumatic diseases.
- Identification of genetic factors for rheumatic disease etiopathogenesis is likely to assist in prediction of risk, early diagnosis and intervention, differential diagnosis and resolution of clinical heterogeneity, determination of variation in response to treatment, and discovery of novel drug targets.

INTRODUCTION

A genetic basis for the majority of rheumatic conditions is now established, and for a small number of these diseases the genetic contribution is clear and can be attributed to a disease-causing mutation in a single gene. Examples of such monogenic disorders include some cases of multiple epiphyseal dysplasia and periodic fever. For single-gene disorders, penetrance of the disease-causing allele may not always be complete (i.e., the presence of a mutation may not result in the full disease phenotype), although the conditions are inherited in a strict mendelian fashion in either a dominant or a recessive manner.

In contrast, the more common rheumatic diseases are not inherited as a simple mendelian trait but are the cumulative result of multiple genetic and environmental effects. The challenge of identifying risk factors for these complex diseases is significantly greater; however, in the past few years, significant advances in the characterization of variations across the genome and the development of high-throughput, accurate, and affordable technologies for single nucleotide polymorphism (SNP) genotyping have resulted in major advances in the identification of genetic loci for complex diseases. The focus of this chapter is to describe the current approaches used to identify susceptibility loci for complex diseases and, in particular, to illustrate how, since the introduction of SNP-based whole-genome association studies in 2007, knowledge of complex disease risk loci, using rheumatoid arthritis (RA) as an example, has increased exponentially. The genetics of a number of monogenic musculoskeletal disorders and the complex diseases of RA, ankylosing spondylitis (AS), systemic lupus erythematosus (SLE), and osteoarthritis (OA) are described in separate chapters.

COMPLEX RHEUMATIC DISEASES

A large number of rheumatic conditions are now considered to represent complex disease phenotypes, including RA, juvenile idiopathic arthritis, SLE, OA, osteoporosis, and AS. Twin studies have proved useful in confirming the existence of a genetic component to susceptibility and also in estimating the relative contributions of both genetic and environmental effects. Monozygotic twins are genetically identical and thus share 100% of their DNA. If a disease is caused solely by genetic factors, it would be expected

that when the condition develops in one twin, the other twin should also be affected. The proportion of monozygotic twins in which both are affected is referred to as the level of disease concordance. Crude monozygotic twin disease concordance figures reflect approximately the relative contribution of genetic factors and environmental/stochastic events. These estimates can be further refined by comparing concordance rates in monozygotic twins with those observed in dizygotic (nonidentical) twins, who have, on average, only 50% of their genes in common. Because both monozygotic and dizygotic twins usually share early environmental exposure, monozygotic and dizygotic disease concordance figures can be modeled to more accurately measure disease heritability. Monozygotic and dizygotic twin concordance figures for a number of rheumatic conditions are summarized in [Table 11.1](#).¹⁻¹⁰

Many twin studies have been based on relatively small data sets or have suffered from sampling bias and should be interpreted with caution. For RA, estimates of monozygotic twin disease concordance rates range from 12% to 34%. Analysis of the heritability of RA suggests that up to 60% of disease etiology is likely to be explained by genetic factors.¹¹

An alternative strategy for assessing increased familial risk is to compare the levels of disease risk in close blood relatives of probands (affected cases) with those seen in the open population. One measure used is familial disease recurrence risk, and for RA this has been calculated as being between 2 and 10.¹² Thus, the disease is 2 to 10 times more likely to develop in first-degree relatives of patients with RA than in individuals without an RA-affected relative. This approach has been further modified to take account of how rare or common a disease is in the population. The coefficient of familial clustering (λ_s) was defined by Risch¹³ as a measure of how much genetic or shared environment component is involved in the etiology of a disease. It is calculated by dividing the sibling recurrence risk by the population prevalence. Depending on which published figures for RA sibling risk and prevalence are used, λ_s for RA has been estimated to be between 2 and 10.¹⁴ λ_s values for a range of rheumatologic and autoimmune conditions are summarized in [Table 11.2](#).¹⁴⁻²⁰

RATIONALE FOR INVESTIGATING THE GENETIC BASIS OF RHEUMATIC DISEASES

An understanding of the risk factors for disease has the potential to have an impact on medicine and patient care at a number of points. Knowledge of genetic susceptibility factors could be used to identify individuals in whom modification of lifestyle might be advised to minimize exposure to environmental triggers of disease. Recognizing potential cases before the onset of symptoms or at the very earliest stages of the disease process may identify a window of opportunity in which therapeutic interventions might be used to prevent the development of full-blown disease. These possibilities may be futuristic, however, and more immediately achievable targets include identification of novel targets for therapy. This has already been illustrated in inflammatory bowel disease, in which identification of an association with polymorphisms in the genes involved in autophagy highlighted this pathway for the first time in the pathogenesis of this disorder.²¹ Sirolimus, which is licensed for use in human organ transplantation, is known to have autophagy-promoting as well as immunosuppressant and antifibrotic activities. In psoriasis and type 2 diabetes, recently identified genetic associations have been identified in genes encoding proteins that are already the target of successful therapeutics²²; for example, ustekinumab, a drug that targets interleukin-12 and interleukin-23 receptor, has been used to treat psoriasis.²³

RA is an example of a disease showing considerable heterogeneity in terms of clinical features and disease course, thus making it challenging for

clinicians to identify patients who should be targeted for the most aggressive therapies and those in whom the condition may resolve with little or no intervention. It seems likely that this heterogeneity is genetically determined, and thus identification of genetic markers to predict outcome would have significant clinical utility. Response to therapies is also likely to be genetically determined, and identification of markers to predict the probable response to treatment or identify those at risk for adverse events would have major advantages in improving targeting of expensive therapies. Being able to achieve any or all of the aforementioned will have a significant impact on the diagnosis and treatment of patients and will lead to a more personalized approach to disease.

APPROACHES FOR IDENTIFYING DISEASE GENES

Historically, two different scientific strategies have been used to search for genetic variants that determine susceptibility to disease: linkage and association studies. Traditional parametric linkage analysis, used with great success to identify loci determining monogenic diseases, relies on the use of multi-case extended pedigrees, of the type rarely available for complex rheumatic diseases. In contrast, nonparametric linkage analysis carried out on smaller “affected sibling pair” pedigrees has been used widely to search for complex disease genes. These studies depend on analysis of hundreds of highly informative genetic markers (usually microsatellites) in large numbers of affected sibling pair families. The markers are used to identify regions of the genome shared “identical by descent” by the affected sibling pairs more frequently than expected by chance and therefore likely to contain disease genes. Before the advent of genome-wide association studies (GWASs), linkage studies offered the only method for screening the whole genome in a hypothesis-free approach.²⁴ The success of linkage studies in identifying risk loci for complex diseases was limited because the majority were underpowered based on current understanding of typical effect sizes.

In contrast, association studies are based on comparison of polymorphic markers in cohorts of cases and controls, with a difference in allele or genotype frequency providing evidence that the polymorphism, or one in linkage disequilibrium with it, is associated with disease. The vast majority of

association studies before GWASs were candidate gene investigations based on a limited number of polymorphisms. Sequencing of the human genome and the subsequent exponential increase in the identification and characterization of millions of polymorphic markers were vital to the development of association studies that screen the whole genome. Also critical was the development of technologies for rapid and accurate genotyping of SNP markers in large numbers of samples.

In the past few years, GWASs and targeted association studies have superseded whole-genome linkage for the study of complex disease genetics, so discussion here is limited to these approaches.

Association studies

The principle of association studies is simple and based on the assumption that the marker under investigation is either causally related to disease or strongly correlated with the causal variant (i.e., in linkage disequilibrium). A difference in allele or genotype frequency between groups of cases and controls provides evidence of disease association of the variant under investigation. Before 2007, disease association studies targeted candidate genes or were the approach used to fine-map linkage peaks. The advent of technologies facilitating accurate, high-throughput genotyping of hundreds of thousands of SNPs has heralded the era of GWASs in which association studies screening the genome in a hypothesis-free manner are carried out by using 0.5 to 1 million SNPs and large numbers of cases and controls.

Provided that basic epidemiologic principles, discussed below, are followed, both candidate gene studies and GWASs are robust approaches and the key methods by which new susceptibility loci will be identified and characterized.

Selection of cases and controls

Perhaps the most common reason given for false-positive associations is population stratification. This problem arises when the population studied contains subpopulations that differ both in allele frequency and in the prevalence of the disease under study. Differences in allele frequency between ethnic groups are well documented, and most studies endeavor to take cases and controls from the same ethnic group. Methods to test and correct for population stratification have been available for some time,²⁵ and it is envisaged that panels of markers sensitive to population structure, so-called ancestry markers, will be developed and incorporated into future studies to overcome problems arising from population stratification. GWASs have a built-in opportunity to adjust for population-based differences in cases and controls, and the utility of three different approaches for these large data sets—(1) structured association tests, (2) principal components analyses, and (3) multidimensional scaling—has been demonstrated. The availability of such methods brings an additional advantage to GWASs in that it becomes possible to use large common population controls for studies involving different diseases and different populations, thereby resulting in significant cost savings.²⁶

A further consideration when sampling subjects for association studies is whether the cases are truly representative of the disease group as a whole. This issue is well illustrated by studies of HLA associations in patients with RA. Numerous studies over many years have characterized the HLA-DRB1 associations with RA and have shown quite variable effect sizes.²⁷ What now emerges is that most of the earlier studies and those showing the highest effect sizes tended to be based on hospital-derived cohorts of patients, which typically consisted of those with more severe disease. It was only by the establishment of prospective primary care-based cohorts with longitudinal follow-up, such as the U.K. Norfolk Arthritis Registry, that it was demonstrated that the HLA shared-epitope alleles much less strongly associated with inflammatory arthritis (odds ratio [OR], 1.8; 95% confidence interval [CI], 1.4 to 2.4). The risk increases for patients satisfying the American College of Rheumatology criteria (OR, 2.3; 95% CI, 1.7 to 3.1) but is strongest for hospital-based studies (average fivefold increased risk), thus suggesting that shared-epitope alleles may be more important in influencing disease severity than susceptibility.²⁸

Power/effect sizes

The power of a study to detect a genetic effect size depends on the sample size of the study and the frequency of the alleles that predispose to disease. Most association studies use similar numbers of cases and controls, although more power is gained by increasing the ratio of controls to cases (a ratio of four times more controls than cases is considered the most efficient). It is now clear that the effect size for the majority of complex disease loci is very small, with the majority identified so far having ORs below 1.5, thus emphasizing the importance of using adequately powered studies, which for GWASs of most diseases means sample sizes of many thousands.

Selection of genetic markers

Candidate genes for association studies have tended to be selected on the basis of knowledge of pathological and biologic processes. SNPs have been the markers most commonly used, largely because they are most easily genotyped. Three major initiatives have focused on the identification and characterization of SNPs, and as a result it is now possible to select markers in a systematic and efficient manner to ensure coverage of common variation (minor allele frequency >1%) for a given locus or gene. First, sequencing of the human genome provided a template against which genetic variation could be studied and mapped; second, the availability of markers was dramatically increased by characterization of millions of polymorphic markers (www.ncbi.nih.gov/SNP); and third, patterns of linkage disequilibrium between markers (www.hapmap.org) have been defined with data generated from four populations (Yoruba, Nigeria, $n = 90$; North American whites living in Utah, $n = 90$; Han Chinese, $n = 45$; and Japanese, $n = 44$). More recently, the 1000 Genomes Initiative (www.1000genomes.org), which involves complete resequencing of the genome in samples from three populations, has revealed further detail of genetic variation between individuals and populations.

The presence and knowledge of linkage disequilibrium between markers mean that it is usually unnecessary to type every known variant at a locus of interest. Data for untyped polymorphisms can be imputed with programs such as IMPUTE.^{29,30}

Analysis and interpretation of results

Applying a significance threshold of $P = .05$ means that 1 in 20 observed associations will have occurred by chance. Performing multiple tests, such as following a GWAS, without adjustment of the threshold is certain to generate false-positive findings.³¹ Applying a Bonferroni correction is thought to be overly conservative, particularly if SNPs are in linkage disequilibrium with each other. An alternative is to perform permutation testing to empirically test the probability of having observed an association by chance.³² The issue of multiple testing is key to the interpretation of GWASs based on a comparison of many hundreds of thousands of markers. A generally accepted threshold for the current generation of GWASs (500,000 to 1 million SNPs) is $P < 5 \times 10^{-8}$.

Replication of the findings in an independent cohort provides compelling evidence that the original result was real and not a false-positive finding.

An interesting phenomenon in this context is the “winner’s curse” whereby there is an upward bias in effect sizes reported in the first published study.³³ This has been shown in a study of 55 meta-analyses, which demonstrated that subsequent studies showed weaker or no association when compared with the original studies.³⁴ Hence, follow-up studies should at least be powered to detect effects at the lower limit of the confidence interval around the OR of the first study.

SUCCESSFUL EXAMPLES OF CANDIDATE ASSOCIATION STUDIES

The first genetic associations in rheumatic diseases were identified some 30 years ago and involved alleles of genes located in the HLA region.³⁵⁻³⁷ Since then, many other associations between HLA antigens and a wide range of rheumatic diseases have been reported, a considerable number of which have been replicated. A summary of these associations is reported in Table 11.3.^{3,27,37-53} A detailed discussion of how HLA may contribute to the etiology of RA is presented elsewhere (see Chapter 89).

Protein tyrosine phosphatase N22

PTPN22 is one of a number of protein tyrosine phosphatase genes involved in regulating the immune response. A functional polymorphism of the PTPN22 gene, 1858C>T, was initially found to be associated with type 1 diabetes.⁵⁴ Subsequently, researchers performed a large-scale case-control association study of candidate genes for RA (16,000 SNPs) and found that the most significant association was with the same nonsynonymous SNP identified in the type 1 diabetes study.⁵⁵ The initial association with RA has since been replicated in all the studies that have followed.⁵⁶⁻⁶³ Association with the same SNP has been found in juvenile idiopathic arthritis,⁵⁶ SLE,^{58,64-66} autoimmune thyroid disease,⁶⁷⁻⁷¹ and a number of other autoimmune diseases.⁷² Interestingly, the 1858C>T variant is found only extremely rarely in the Asian population, and there is no evidence that PTPN22 has a role in susceptibility to RA in Asians. Despite the fact that the disease-associated variant in PTPN22 resulted in an amino acid change, elucidation of the functional impact of this variant has proved surprisingly difficult and has served to demonstrate the importance of considering cell specificity for functional biology experiments.^{73,74}

WHOLE-GENOME ASSOCIATION STUDIES OF RHEUMATOLOGIC CONDITIONS

The proof-of-principle investigation that demonstrated the practicality and utility of GWASs came in 2007 from the Wellcome Trust Case Control Consortium (WTCCC), which undertook a genome-wide analysis of seven common diseases, including RA. The Affymetrix Gene Chip 500k Mapping Array Set was used to genotype 500,000 SNPs in 2000 cases with each of seven diseases and in a set of 3000 common controls, all samples from white U.K. residents.⁷⁵ For RA, markers in the *HLA-DRB1* and *PTPN22* gene regions were highly significantly associated with disease ($P < 5 \times 10^{-7}$). Strong but not incontrovertible evidence of association was detected to more than 50 additional loci ($P < 10^{-4}$ to 5×10^{-7}) (Fig. 11.1). Analysis of markers from these loci in large independent sample sets has since confirmed RA loci at 6q23,⁷⁶ 10p15, 12q13, and 22q13,⁷⁷ thus implicating the genes *TNFAIP3*, *PRKCQ*, *KIF5A*, and *IL2RB*. Further GWASs in different populations and meta-analyses of GWASs providing ever greater power have led to the identification of more than 60 RA loci in all populations (Fig. 11.2).⁷⁸⁻⁸⁰

Successful GWASs have now been carried out for all the major rheumatologic conditions, including SLE,^{81,82} AS,⁸³ OA,⁸⁴ psoriatic arthritis,⁸⁵ juvenile idiopathic arthritis,⁸⁶ and systemic sclerosis.⁸⁷ In all cases the studies have both confirmed some of the established associations and identified new susceptibility loci.

GWASs can now be carried out as a matter of routine. The challenge remains to distinguish all true-positive associations from among a considerable number of highly significant results arising as false positives. Increasing sample sizes and meta-analyses offer one solution, but bioinformatics has great potential to assist in this challenge. A computational method (GRAIL) that applies statistical text mining to PubMed abstracts has been used with success across a number of diseases. It was used to prioritize association signals with a functional connection to established RA loci from signals with relatively weak evidence of association in the GWAS data ($P < .001$) for investigation,⁸⁸ and as a result, further RA loci were identified.

Genes for a number of RA-confirmed loci are known to function in T- and B-cell signaling pathways, and it is likely that additional genes involving the same or related pathways may harbor risk alleles. The considerable overlap between loci identified for RA and those identified for other autoimmune diseases, including type 1 diabetes and celiac disease (Fig. 11.3), is quite amazing and implicates common dysregulated immune pathways. It appears that the vast majority of susceptibility loci identified for arthritic diseases are not unique to one disease.⁸⁹

TIMELINE OF THE DISCOVERY OF RA SUSCEPTIBILITY LOCI, ILLUSTRATING THE IMPACT OF GWASs

Fig. 11.2 GWASs, genome-wide association studies; RA, rheumatoid arthritis.

Although rapid progress has been achieved in the identification of disease susceptibility markers implicating genetic loci, for the most part our understanding of these loci and how associated alleles cause disease is very limited. The next key step will involve in-depth characterization of the genetic architecture at each locus. Subsequently, understanding how associated variants affect function will require an array of approaches but is likely to benefit considerably from the ENCODE initiative,⁹⁰ a program aimed at annotating all protein coding sequences in the genome.

NEW HORIZONS

Progress in complex disease genetics has been driven largely by staggering advances in technology and computer-based informatics. Although it took a major international consortium with teams of scientists and many DNA-sequencing machines 10 years to complete the sequencing of the human

Fig. 11.3 Illustrated here are some of the loci identified for type 1 diabetes (T1D), celiac disease (CD), and rheumatoid arthritis (RA). The specific markers associated with each disease may differ.

genome, we are now entering an era when resequencing the genome of an individual is possible in hours at affordable prices. The impact that such information could have on medicine in general and rheumatology in particular is hard to imagine.

Furthermore, the postgenome era has led to a greater realization that disease etiology and processes should not just be viewed one-dimensionally from the level of gene sequences but, rather, how these sequences are transcribed differently by differentiated cells and how such transcripts are translated into proteins. The great expansion in complexity that increases from approximately 20,000 genes in the human genome to an estimated 300,000 different proteins, largely through alternative gene splicing and posttranslational protein modification, including epigenetic modifications, is becoming better appreciated. The way that such proteins interact and the metabolic processes and products that result are now providing important insight into unraveling disease processes and pathways. Scientists are now increasingly realizing that a holistic approach has to be taken to fully understand disease etiopathogenesis. The development of genomic technologies such as transcriptomics, proteomics, and metabolomics is being powerfully combined with genomics into an approach called "systems biology." This is increasingly driving translational medicine and is anticipated to have a major impact on rheumatology.

Full translation of the information that resides in our genome and how it relates to complex diseases will come only through understanding how it interacts with environmental factors. These factors could be gene-nutrient, gene-microbiome, gene-lifestyle (e.g., alcohol/smoking), or gene-drug (pharmacogenetics) interactions. Such studies are difficult, and many can be appropriately addressed only through large longitudinal population-based cohorts in which premorbid environmental exposure data and biological samples can be collected.

There is increasing realization that response to drug treatment, in terms of both efficacy and adverse reactions, is largely encoded within our genes, and this is poised to have great impact in the field of rheumatology. Pharmacogenetic studies are already beginning to explain why some patients are resistant to some second-line drugs or have reactions to drugs such as azathioprine. The next 5 years in the genetic study of rheumatic disease will undoubtedly be very interesting.

Principles and techniques
in molecular biology

■ ELAINE F. REMMERS ■ MICHAEL J. OMBRELLO ■ RICHARD M. SIEGEL

- Restriction enzymes, DNA and RNA polymerases, DNA ligases, reverse transcriptases, phosphatases, kinases, and thermostable DNA polymerases are enzymes used to clone, modify, and amplify DNA in the laboratory.
- Incorporation of exogenous DNA fragments into vectors that can replicate in bacteria, yeast, or insect cells permits large-scale production of the cloned gene or encoded protein.
- Massively parallel high-throughput sequencing, which allows for the simultaneous analysis of nucleic acid sequence at billions of positions, is an extremely powerful tool that facilitates genomewide or transcriptome-wide investigations of both mendelian and complex genetic traits.
- Northern blot and real-time polymerase chain reaction are methods that quantitatively measure the expression of specific genes, whereas microarray expression profiling and RNA sequencing simultaneously evaluate the expression of thousands of genes.
- Electrophoretic mobility shift assays and chromatin immunoprecipitation assays detect DNA interactions with proteins, such as transcription factors and modified histones that are regulators of gene expression.
- Transfection methods are biochemical, physical, or viral techniques for transferring exogenous DNA into cultured cells for expression. In a variant of the method, the expression vector directs transcription of short inhibitory RNAs that block the endogenous gene's expression.
- Transgenic mice are genetically modified animals into which an exogenous DNA construct has been transferred, whereas in knockout mice the endogenous gene has been disrupted, which thereby prevents its expression.
- Protein-protein interactions can be analyzed by coimmunoprecipitation and yeast two-hybrid screening. Fluorescence resonance energy transfer can be used to evaluate protein-protein interactions in living cells.

INTRODUCTION

The past decade has witnessed rapid advancement in genomic medicine, driven initially by the Human Genome Project and subsequently by the 1000 Genomes Project and other large-scale, population-based genomic sequencing efforts. Together, these projects continue to reveal the scope and complexity of genetic and genomic variation in human beings, and they continue to afford scientists and physicians extraordinary opportunities to advance our understanding of physiology and pathology.¹ Until just a few years ago these possibilities were more science fiction than science. However, a number of critical technologic breakthroughs have truly revolutionized biomedical research. The opportunities for improving our understanding of rheumatic and autoimmune diseases are now astounding. Moreover, it is likely that recent advances will accelerate the pace at which disease susceptibility genes are identified and their functions analyzed. It is likely that this information will also improve treatment and propel the discovery of new therapeutic modalities.

It is therefore intended in this chapter to review the basic tools that rheumatologists now see being employed when they read the literature.

Given the space constraints, the chapter does not review basic concepts in DNA replication, transcriptional control, and signal transduction. There are several excellent textbooks that cover these topics.^{2,3} Rather, the focus is on the methods used to study these processes, but the intent is not for this to be a laboratory manual or “how to” guide; again there are ample sources that provide detailed protocols of this sort.^{4,5} Instead, the goal is to present the principles underlying important techniques with which the average rheumatologist should be familiar to comprehend studies that are pertinent to clinical work. Skimming through the rheumatologic literature one sees references to a variety of techniques such as next-generation sequencing, RNA sequencing, chromatin immunoprecipitation sequencing, electrophoretic mobility shift assays, microarrays and gene expression profiling, and tissue-specific knockouts using the cre/lox system. This chapter will therefore discuss some of the major techniques and their modifications to facilitate comprehension of the literature.

THE HUMAN GENOME SEQUENCE AND
BIOMEDICAL RESEARCH

The human genome consists of about 3 billion adenine (A), guanine (G), cytosine (C), and thymine (T) bases (Fig. 12.1) arranged in 23 pairs of chromosomes. A great surprise was that the immense amount of potential genetic information encodes a relatively small number of genes, fewer than 30,000,^{6,7} which makes humans about twice as complex as model organisms such as yeast and *Drosophila* but less complex than rice. It is important to emphasize, however, that alternative splicing and protein modifications greatly increase the complexity of the polypeptides encoded by the human genome.

The onslaught of information brought about by the Human Genome Project, the 1000 Genomes Project, and other similar large-scale sequencing projects have provided both new opportunities and new challenges to investigators. DNA and protein sequences, sequence variation, expression data, and structural data are among the information being deposited into a growing number of public and private databases. Savvy investigators can mine these databases to obtain useful information with a variety of search and computational tools. Many publicly accessible databases and tools are available at the National Center for Biotechnology Information website (www.ncbi.nlm.nih.gov/). Tools such as BLAST (Basic Local Alignment Search Tool), which facilitates sequence comparisons, can be used, for example, to find additional members of gene families that may have functions similar to one another. Comparisons of homologous genes of several species can identify regions that are conserved among species. These elements may be expressed parts of genes or unexpressed regions that may be conserved because they contain important regulatory elements. Managing and analyzing the data derived from genomewide approaches to expression profiling and disease-gene linkage and association studies can also require sophisticated computational and organizational approaches. The computational power, statistical sophistication, and computer programming skills required for development and implementation of tools applicable to biologic problems have resulted in rapid explosion of the field of bioinformatics, surely an area that will continue to grow for the foreseeable future.^{8,9}

The molecular biology revolution, of course, began long before the Human Genome Project. Major steps in the revolution were the development of techniques that permitted the *in-vitro* manipulation of DNA and advances in large-scale DNA sequencing. These advances permitted the identification, sequencing, isolation, and expression of genes, which allowed their functions to be discerned.

BASIC MANIPULATION OF DNA: CLONING VECTORS AND CUTTING AND PASTING DNA USING ENZYMES

Vectors are engineered DNA molecules used to replicate, isolate, and express foreign DNA. There are several general types of commonly used vectors, which were derived from bacteria and bacteriophage.

Plasmids are extrachromosomal, double-stranded circular DNA molecules. Often they are relatively small (3 to 5 kb), and they have three important features: a drug selection marker, convenient cloning sites, and a replicator that permits autonomous replication in cells (Fig. 12.2). Some plasmids also have mammalian promoters that permit expression of the protein in mammalian cells, whereas others are designed for expression in bacteria, yeast, or insect cells, the last being a very efficient means of generating large quantities of protein for crystallography studies. Sometimes, plasmids are constructed to permit the production of fusion proteins.

A commonly used vector permits cloning of a given gene in frame with glutathione *S*-transferase (GST). Glutathione-coupled agarose beads bind GST with high affinity and allow one to do “pull-down” experiments (see later). Another commonly used technique is to fuse the protein of interest to green fluorescent protein (GFP), a protein made by jellyfish, which can be easily visualized within cells (Fig. 12.3).¹⁰ Remarkably, most fusions to

GFP retain the localization properties of the original protein molecule, provided that expression levels are not extremely high. As discussed later, this permits one to visualize trafficking of molecules in cells by live cell imaging. This is aided by the fact that fusion fluorescent proteins can now be engineered in a wide variety of colors from blue to far red, which permits simultaneous detection of multiple proteins and studies of protein-protein interaction by fluorescence resonance energy transfer.¹¹

The bacteriophage λ has been a heavily used tool in molecular biology for many years. Its genome is about 50 kb, but the central portion of the viral genome is not essential for lytic growth and can be replaced by 10- to 20-kb inserts; for this reason, it is a commonly used vector to create libraries of genes. Cosmid vectors are hybrids between λ and plasmid vectors that can accommodate larger inserts of foreign DNA (35 to 50 kb). P1 vectors are derived from bacteriophage P1 and are large, circular DNA molecules that can contain 70 to 100 kb of eukaryotic DNA. P1-derived artificial chromosomes can accommodate even larger DNA inserts (up to 150 kb), whereas bacterial artificial chromosomes have a still larger insert capacity (up to 200 kb) and have become the preferred vector for sequencing large DNA fragments and are used for multiple purposes, including generation of transgenic mice. Although yeast artificial chromosomes can accommodate even larger DNA inserts (about 1 Mb), these vectors are used less frequently because of problems with instability and chimerism. Finally, vectors derived from the M13 filamentous bacteriophage can accommodate small inserts

Fig. 12.1 Although the human genome is less complex than initially thought in terms of the actual number of human genes, regulatory phenomena such as alternative splicing may considerably increase the diversity of proteins produced.

Fig. 12.3 The ability to visualize the trafficking of cell proteins by tagging them with green fluorescent protein (GFP) has revolutionized cell biology and cell signaling. In this case, the *Cybr* gene is fused to GFP (green). Actin is visualized by binding of rhodamine-labeled phalloidin (red), and nuclei are stained with 4',6-diamidino-2-phenylindole (blue). (Courtesy Dr. Massimo Gadina, National Institute of Arthritis, Musculoskeletal and Skin Disease, National Institutes of Health.)

Fig. 12.2 Abundant commercially available enzymes (ligases, polymerases, and restriction enzymes) and vectors make the *in-vitro* manipulation of nucleic acids feasible. Amp^r, ampicillin resistance gene; GFP, green fluorescent protein; MCS, multiple cloning site; Ori, origin of replication; RE, restriction enzyme.

(up to 1 kb) and can be used to produce single-stranded or double-stranded DNA.

Libraries containing many different inserts representing different genes can be made using most of the aforementioned vectors. Libraries are made using genomic or complementary DNA (cDNA) and in some cases can permit expression of the gene encompassed by the insert.

Many different enzymes are commercially available that permit replication and joining of DNA; such enzymes are termed *DNA polymerases* and *ligases*. Modifying enzymes such as phosphatases and kinases are also important in DNA ligation reactions. Exonucleases and endonucleases cut DNA, whereas restriction enzymes are bacterially derived enzymes that cut DNA at specific sites. These are among the most important tools in molecular biology. Hundreds of restriction enzymes are commercially available that allow one to cut DNA in a predictable manner.

With the use of the enzymes just listed, pieces of DNA can be copied and spliced into vectors, which allows large-scale production of the gene or the encoded protein. An example of how these different enzymes can be used to move a piece of DNA from one vector to another is provided in Figure 12.2. RNA also can be synthesized from DNA by DNA-dependent RNA polymerase, and the RNA, in turn, can be translated *in vitro* into protein. Conversely, reverse transcriptase, derived from retroviruses, synthesizes DNA from RNA. This enzyme is used to make cDNA and to make libraries from messenger RNA (mRNA) and can be the starting point in the polymerase chain reaction.

POLYMERASE CHAIN REACTION

The polymerase chain reaction (PCR) is a rapid procedure for *in-vitro* amplification of DNA; the development of this procedure was another landmark in molecular biology. There are a large number of applications of PCR, including the following:

- Cloning of genomic DNA or cDNA
- Mutagenesis or modification of DNA
- Assays for the presence of pathogens
- Detection of mutations
- Analysis of allelic sequence variations
- Genetic fingerprinting of forensic samples
- Nucleotide sequencing

A schematic of PCR is shown in Figure 12.4. The reaction includes the following components: a segment of double-stranded DNA to be amplified (template); two single-stranded oligonucleotide primers, each complementary to one of the two template strands; and deoxyribonucleoside triphosphates. Another critical component is a heat-stable DNA polymerase such as *Taq* polymerase. Its heat stability is an essential feature because the enzyme must withstand repeated cycles of heating and cooling to denature and replicate the target sequence many times. PCR takes place in a device termed a *thermocycler*, which can rapidly change the reaction temperature.

First, the double-stranded DNA template is heated to generate single-stranded DNA. The primers, added in vast excess compared with the template DNA, anneal or hybridize to opposite strands of single-stranded DNA. The DNA polymerase then synthesizes new strands of DNA complementary to the template. After the first round of synthesis the reaction mix is again heated, with subsequent denaturation of the double-stranded DNA, annealing of primers, and synthesis of DNA. These cycles permit a millionfold amplification of DNA. By designing particular primers, one can mutagenize DNA or add cloning sites.

An important application of PCR is to detect RNA transcripts or to amplify their sequences to permit cloning and/or sequencing. This requires first converting RNA templates to cDNA using reverse transcriptase (RT-PCR).

DNA SEQUENCING

Manual techniques to sequence DNA were devised in the 1970s; however, sequencing the human genome was made possible by the development of automated sequencing technology. This technology continues to play an important role in the rheumatology research laboratory and is beginning to be applied as a diagnostic tool. In the research setting, DNA sequencing is being used to refine the human genome sequence and to provide information regarding normal and disease-associated variation in the human genome. Sequencing cDNAs constructed by reverse transcription of mRNA can provide information regarding the structure of gene products. The DNA sequence is also obtained to confirm the structure of cloned DNA and

Fig. 12.4 The use of thermostable DNA polymerases and automated thermocyclers permits vast amplification of DNA and RNA templates through the polymerase chain reaction (PCR) method. Double-stranded DNA (template, light blue) is denatured by heat and, when cooled, primers (dark blue) anneal, which allows synthesis of new DNA (broken line, lavender). These cycles of denaturing, annealing, and synthesis are repeated with continued amplification of DNA (green). One can start with double-stranded DNA or with messenger RNA and use reverse transcriptase to generate the first complementary DNA strand, which is further amplified as earlier. PCR has many applications, ranging from diagnostics to mutagenesis, and has become an indispensable laboratory tool.

manipulated DNA constructs used for expression, gene transfer, or gene-targeting experiments.

In the clinical setting, several rheumatic diseases are now known to be genetic disorders for which mutations have been identified. These include several of the periodic fever syndromes, as well as some musculoskeletal disorders such as Marfan syndrome and familial osteochondral dysplasias causing early-onset osteoarthritis. For such disorders, sequencing can be used as a diagnostic tool, for example, to confirm the diagnosis of familial Mediterranean fever, which might be confused with a number of different inflammatory disorders. A definitive diagnosis permits the clinician to apply the most effective therapy as a treatment instead of using response to the therapy as a diagnostic tool.

Sequencing by the Sanger method¹² requires isolated DNA fragments specifically amplified by cloning or PCR. Complementary strands are synthesized by complementary base pairing on denatured DNA templates using enzymes (DNA polymerases) that normally perform this job in replicating cells. There are several variations on the strategy to obtain the sequence of the DNA fragment automatically. In the most common variant, four different fluorescent dye-labeled "terminator" analogues of the four deoxyribonucleotides, which incorporate into the growing strand but then terminate the reaction, are included in the replication mix (Fig. 12.5). The dye-labeled fragments are then separated by size through gel or capillary electrophoresis. The dye associated with each fragment identifies the last nucleotide analogue incorporated. The sequence can then be automatically read by detecting the succession of dyes detected as the fragments move through the separation medium. The initial sequencing of the human and mouse genomes was accomplished using these automated sequencing instruments.

A landmark event in the evolution of nucleic acid sequencing was the emergence of massively parallel high-throughput sequencing methods, referred to in aggregate as next-generation sequencing (NGS). NGS approaches simultaneously generate sequence information at tens to hundreds of billions of base pair positions. Because of the substantial time and cost savings

Fig. 12.5 Sequencing of DNA is performed by extending oligonucleotide-primed DNA templates with a thermostable DNA polymerase in the presence of dye-tagged dideoxy terminators that block further extension of the newly synthesized DNA strand and label the strand with one of four different fluorescent dyes identifying the last base incorporated. Automated methods for size fractionating the fragments, detecting the fluors, and reading the DNA sequence have made possible the large-scale sequencing required for sequencing the human genome.

of NGS, compared with traditional sequencing methods, NGS has ushered in an era of genome-level sequencing projects that were previously unimaginable. Although there exists an ever-growing number of NGS platforms and techniques,¹³ they each share a central schema which includes preparation of a library of DNA templates, sequencing and imaging of the template library, and finally analysis of the data. A general example of this process is depicted in Figure 12.6.

Creation of a library of DNA templates is the starting point for NGS, and a range of strategies may be employed in library creation. Whole-genome sequencing uses DNA libraries created from whole genomic DNA, in contrast to target-enrichment strategies, which extract from the whole genomic DNA only those regions of interest. Target enrichment may be accomplished by a variety of methods, each of which effectively captures and separates the DNA segments of interest for library preparation. Exome sequencing, the most widely adopted target-enrichment strategy, seeks to capture and sequence the coding regions of the genome. In general, the DNA template library is generated by first breaking the genomic DNA into homogeneously sized fragments that are then ligated to adapter molecules on both ends. These adapter molecules facilitate the immobilization of DNA templates onto glass slides or beads, which produces a spatial distribution of DNA templates that allows for each of them to be imaged independently. In some

cases, the immobilized DNA templates are amplified with universal primer sequences contained within the adapters, which transforms each DNA template into a cluster of identical DNA molecules. In other cases, the signal intensity generated by a single DNA template molecule is adequate for detection, and no DNA template amplification is required.

Upon generation of a library of DNA templates, most NGS approaches use dye-labeled nucleotides that are specifically incorporated during cycle sequencing and are subsequently imaged. After the imaging step of each cycle, the labeled nucleotides are modified to remove the dye molecules and to allow progression of the next cycle of incorporation and imaging. Although the chemistry and experimental design vary among platforms, every NGS platform requires the sequential imaging of fluorescent signals at fixed locations to facilitate and assemble sequence reads from the DNA templates or clusters.

The raw data generated by NGS consist of a very large number of sequence reads, the lengths and configuration of which are dictated by the platform and experimental design used for the sequencing. These sequence reads must be aligned to a known reference sequence to allow for identification of variant alleles. In some cases it may be beneficial to first assemble the sequence reads with one another in the absence of the reference sequence, referred to as *de novo* assembly. In the case of structural variants, gene families with a high degree of homology, or regions rich in repetitive elements, sequence reads may align with multiple genomic locations in the reference sequence and as a result may be excluded from subsequent analysis. With *de novo* assembly, one attempts to harness the power of the overlapping sequence reads to place these otherwise multiply-mapping reads into their correct genomic position. Once the sequences have been assembled and aligned, one may generate a list of positions at which the experimental sample differs from the reference, and rapidly evolving bioinformatic tools can annotate sequence variants based upon characteristics such as the type of variant, the depth of coverage or quality scores of a variant, the degree of conservation of that reference position across other organisms, and the predicted effect of the variant on its protein product.

Even when sequencing is performed by the most experienced sequencing centers and bioinformaticians, errors are inescapably introduced at multiple steps of the NGS workflow, leading to an errant base call rate as high as 1%.¹⁴ Potential sources of error are widespread and may include the limited fidelity of polymerase enzymes during the whole-genome amplification or cluster amplification processes, the incorporation of degraded dye-labeled nucleotides or the misincorporation of dye-labeled nucleotides during cycle sequencing, the presence of optical interference that precludes proper identification of bases, and the false-positive and false-negative variant identification that may result from erroneously mapped sequence reads. In response to this problem, there is a rapid emergence of both experimental and bioinformatic approaches that promise to better identify erroneously called variants. At this point, validation of NGS findings by Sanger sequencing remains the gold standard.

GENE TRANSCRIPTION

Insights into the physiologic and pathologic functions of a given gene may be gained by analyzing the expression of its mRNA in tissue and cells and delineating when, where, and how the gene is regulated. Northern blotting and quantitative real-time PCR are useful to measure the level of gene expression of one or a few genes, and *in-situ* hybridization can be used to show the gene expression in tissue.

RNA is often isolated using acid guanidinium-phenol-chloroform-based methods and in some cases is further purified by oligo-dT columns with immobilized short sequences of deoxythymine nucleotides, which bind the poly A tail of mRNA. In Northern blotting, RNA is separated by size in an agarose gel, transferred to a membrane, and detected by a labeled probe using RNA-DNA hybridization. The amount of mRNA corresponds to the binding of the radioactive probe, which can be visualized by autoradiography.

In real-time PCR, a quantitative method for measuring mRNA, mRNA is transcribed into cDNA by reverse transcriptase (Fig. 12.7). A probe with a fluorescent dye at its 5' end and a quencher dye at the 3' end is added to the reaction tube. During the PCR reaction, the reporter dye is separated from the quencher dye; DNA polymerase has 5' nuclease activity, which degrades the hybridized probe as a new DNA strand is synthesized in its place. When the reporter dye is separated from the associated quencher dye, its fluorescence is detected and accumulates with each successive round of PCR. Generation of the fluorescence is quantitatively dependent on the number of transcript copies in the cDNA sample. A reference probe for a housekeeping gene is also included, which allows this to be a quantitative assay. Because of the use of PCR, this technique is very sensitive, and

Fig. 12.6 Next-generation sequencing permits simultaneous generation of sequence information at tens to hundreds of billions of base pair positions. (a) A library of DNA templates is created by fragmenting double-stranded genomic DNA (ds gDNA) into small, single-stranded pieces (ssDNA) to which adapter molecules are attached. (b) The DNA templates are immobilized to slide-bound adapter molecules, and through the use of oligonucleotides that recognize primer sites within the adapter molecules, cluster amplification transforms each immobilized DNA template molecule into a cluster of identical DNA templates. (c) Cycle sequencing begins with single-base-pair incorporation of dye-labeled nucleotides onto each DNA template molecule. The unbound dye-labeled nucleotides are thoroughly washed and removed, after which fluorescent images are captured for each cluster of DNA templates. The dyes are then cleaved from the incorporated nucleotides, and the subsequent cycle of sequencing begins again with the incorporation dye-labeled nucleotides at the next position of each DNA template.

methods have been developed to quantitate gene expression from single cells with a commercial platform using microfluidics, which allows profiling of a set of genes from single cells. These studies can highlight the heterogeneity in gene expression among cells in an apparently identical population that may have impact on their function or developmental potential.¹⁵ Ribonuclease (RNase) protection is another means of measuring mRNA and has the advantage that multiple genes can be analyzed simultaneously. In this method, labeled antisense riboprobes are hybridized to RNA in solution and then digested with RNase, which digests single-stranded but not double-stranded RNA. The amount of riboprobe protected by the mRNA is therefore

a measure of the gene expression. Another method to quantify multiple different mRNA molecules has recently been developed and is commercially available (NanoString Technologies Inc., Seattle). This method uses a two-probe barcoded detection system¹⁶ that can make direct measurements of the abundance of up to 800 RNA species in RNA from as few as 10,000 cells without enzymatic reactions or bias.

In-situ hybridization identifies which type of cell in a tissue expresses a particular gene. In this method, one hybridizes a specifically labeled nucleic acid probe to the cellular RNA in individual cells or tissue sections. In principle, this employs the same strategy as Northern blotting

Fig. 12.7 In quantitative real-time polymerase chain reaction (PCR), oligonucleotide probes coupled to a reporter dye are synthesized along with ordinary primer pairs and used in the reaction. The intact probe does not fluoresce because a quencher is also coupled to the probe. However, the probe is cleaved by DNA polymerase during amplification, which separates reporter dye from quencher dye and results in increased fluorescence. The amount of PCR products generated can therefore be measured by monitoring the intensity of fluorescence with each cycle, because the amount of probe cleaved parallels the amount of PCR products produced. This is a reflection of the initial amount of complementary DNA (cDNA) generated from messenger RNA. This test can be further standardized by including probes and primers for housekeeping genes and can be made more quantitative by generating a standard curve using known amounts of cDNA encoding the gene of interest.

(hybridization of RNA with labeled cDNA), but in this case the hybridization is visualized within cells using microscopy. The gene's protein product or other proteins can also be visualized by immunohistochemistry, which may be quite informative in the analysis of clinical samples or in assessing the role of the gene in development.

The steady-state levels of mRNA are influenced by several factors, including the rate of its transcription as well as its stability, transport, and translation. The nuclear run-on assay measures the levels of primary transcript production without influence of other factors and thus can be used to distinguish whether a change in mRNA level is due to a difference in the rate of transcription per se or to other reasons such as altered mRNA stability.

EXPRESSION PROFILING

Although expression of genes can be evaluated by *in-situ* hybridization, RNase protection assay, Northern blotting, or quantitative real-time PCR (see earlier), the selection of genes for study is limited by the extent of our prior knowledge. New technologies building on the identification of most expressed genes by the Human Genome Project and more recently using high-throughput sequencing permit expression profiling; that is, analysis of the expression of thousands of genes, including those with unknown function, in a tissue or cell population. Indeed, these newer methods permit evaluation of the expression of not just a few genes but potentially *all* genes.

Several techniques have been developed for expression profiling. In serial analysis of gene expression, a small tag (short DNA fragment) is generated from each transcript. The tags are concatenated, and these larger DNA fragments are sequenced to identify the transcripts as well as their frequency in the transcript pool derived from a tissue or cell population.¹⁷ Array-based

methods of expression profiling use specific nucleic acid probes immobilized in an ordered array on a solid surface. Hybridization techniques in which labeled cDNA or cRNA fragments bind to the immobilized probes are then used to estimate the relative number of copies of each gene transcript in RNA extracted from a tissue or cell sample by the amount of label that binds to the immobilized probe. To achieve probe density sufficient to assay expression of tens of thousands of genes from relatively small tissue or cell samples, microarray technology was developed. There are two commonly used expression-profiling microarray techniques: DNA chip microarrays and spotted DNA arrays. In the DNA chip microarray technique the probes are oligonucleotides synthesized on the surface of a DNA chip or attached to the surface of beads that are affixed to the surface of a slidelike bead array; in the second technique they are fragments of cDNA clones or synthetic oligonucleotides that are spotted onto the surface of glass microscope slides.^{18,19} The newest methods for expression profiling use NGS technologies to comprehensively characterize and quantify the transcriptome.

DNA chip microarrays

DNA chip microarrays (Fig. 12.8) are manufactured by Affymetrix, Inc. (Santa Clara, Calif.) using a proprietary photolithographic process to synthesize 25-base oligonucleotides tethered to the chip surface; each is confined to a space 11- × 11-μm square. Each gene is represented by 22 squares with oligonucleotide probes covering various parts of the gene. Half the probes are perfect-match and half are hybridization controls, that is, copies of the perfect-match oligonucleotides, each with a single nucleotide mismatch. Probes for up to 47,000 transcripts can be synthesized on a single chip that is less than 1 cm². RNA is extracted from tissue or cells, and cDNA is synthesized. The cDNA is used to produce biotin-labeled complementary RNA (cRNA), which is fragmented and hybridized to the probes on the chip surface. The chips are washed and stained with a streptavidin-conjugated fluorescent dye, which binds to the hybridized biotinylated cRNA. The chips are scanned and the fluorescent signals are processed to determine the expression level of each gene. Normalized expression levels determined from different tissue or cell samples on different chips can then be compared (see Fig. 12.8).

A variant of the DNA chip microarray is the BeadChip microarray (Illumina, Inc., San Diego, Calif.). In this technique beads are coated with oligonucleotide probes (50-mers) attached to an address tag oligonucleotide (30-mers). The beads are randomly affixed to the surface of a slidelike solid support. About 30 beads of each type (representing a single transcript) are affixed to each BeadChip microarray, and their locations are determined by the address tags. Labeled cRNA is produced and hybridized to the BeadChip. The chips are scanned, and the signal intensity for each probe type is measured.

An advantage of DNA chip or bead microarrays is that, because the microarrays are mass-produced under highly controlled conditions, reproducibility of the expression data obtained from them can be very high. A disadvantage is that production of the microarrays is inflexible (custom arrays are expensive). Furthermore, only genes with sufficient sequence data to generate the probes can be represented on a DNA chip microarray.

Spotted DNA microarrays

A somewhat different technique is used for spotted DNA microarrays (Fig. 12.9). The arrays are produced by robotically spotting cDNA fragments or synthetic oligonucleotides onto glass microscope slides. The cDNA fragments are produced by PCR amplification of collections of cloned cDNA plasmids to obtain the cDNA inserts. Up to 40,000 elements can be printed on a single glass microscope slide. Unlike the DNA chip microarrays, in which transcripts from a single sample are hybridized to the array, cDNA transcripts from two samples the investigator wishes to compare are simultaneously hybridized to the spotted DNA microarray. RNA is extracted from the two samples and converted to cDNA in the presence of nucleotides labeled with either Cy3 or Cy5 (fluorescent dyes). The labeled transcripts are then cohybridized to the DNA probes on the microarray. Hybridization signals from the two dyes are used to determine expression ratios for all the genes on the microarray (see Fig. 12.9).

A variant of the cDNA spotted array technique is to spot long oligonucleotides (60-mers) in the place of the cDNA fragments. This change permits selection of a region or multiple regions of a transcript to be used as probes, which allows exclusion of regions that may be involved in nonspecific hybridization as well as separate evaluation of differentially spliced forms of genes.

An advantage of spotted DNA microarrays is that, because the arrays are produced on a small scale, they can be customized, for example to include

Fig. 12.8 With the use of DNA chip microarrays, the expression of tens of thousands of genes can be determined simultaneously using messenger RNA (mRNA) extracted from samples. The mRNA is reverse transcribed to complementary DNA (cDNA), which is *in vitro* transcribed (IVT), producing biotin-labeled complementary RNA (cRNA). The cRNA is fragmented and hybridized to oligonucleotide probes that have been synthesized on the surface of a silica chip. The hybridized cRNA is labeled with a streptavidin-conjugated fluor and scanned for detection. Specific hybridization is gauged by comparison of hybridization to pairs of perfect-matched and single-base-mismatched oligonucleotides, represented in the figure by the blocks directly above and below one another. Approximately 11 pairs of oligonucleotides on the chip represent each gene. The intensity of the specific hybridization signal is a measure of the gene expression in the sample.

newly discovered genes. A disadvantage is that the cDNA clone or oligonucleotide libraries must be acquired for production of the arrays. Furthermore, cDNA microarrays are technically difficult to produce and can be subject to reproducibility problems.

Massively parallel sequencing of RNA

Massively parallel sequencing of RNA (RNA-Seq), which employs NGS to interrogate RNA sequence and abundance, is perhaps the most powerful tool for unbiased investigation of RNA species. RNA-Seq has been most widely used in the investigation of mRNA, in which case the polyadenylated RNA species are captured from a sample. The captured RNA is fragmented to a size of several hundred bases, either before or after producing cDNA by reverse transcription, and the cDNA fragments are concurrently sequenced using NGS technology. Each sequencing read is then assembled and aligned to the human genome, and the prevalence of each RNA species may be determined. In addition to accurately quantifying genomewide expression, RNA-Seq may also identify the presence of variant alleles, alternatively spliced transcripts, posttranscriptional mutations or RNA editing, and gene fusions. Furthermore, using a variety of different RNA capture conditions, RNA-Seq may be modified to interrogate noncoding RNA, micro-RNA, or any other population of RNA. Because of the inherently error-prone nature of reverse transcriptase enzymes, the process of creating a cDNA library may introduce errors and bias to an RNA-Seq study. As a result, efforts are under way to develop protocols to perform RNA-Seq on RNA molecules themselves.

REGULATION OF GENE EXPRESSION AND PROTEIN-DNA INTERACTIONS

Understanding what controls the expression of a given gene is of considerable interest in the pathogenesis of rheumatic diseases. Typically, the first step in the process involves the identification of the promoter and enhancers of the gene of interest. Generally, this is accomplished by identifying the transcriptional start site and the 5' untranslated regulatory portion of the gene. These regions of the gene are then subcloned into reporter systems, which are used as surrogates to measure transcriptional regulation and the interactions of *cis*- and *trans*-acting elements with promoters and enhancers. Typically, regulatory sequences are ligated to reporter genes, such as firefly luciferase, and these plasmids are transfected into cells of interest that are stimulated in various ways. In this manner, the luciferase gene is transcribed in the place of the native gene, and the level of transcription can be detected

by light produced by the translated luciferase protein, which is regulated by stimuli that act on the heterologous promoter (Fig. 12.10). The fine structure of promoter/enhancer regions can be analyzed by introducing a series of mutations and examining the effects on reporter gene expression. The effect of patient-derived mutations or polymorphisms in promoters may also be examined to assess their influence on gene expression.

Identifying transcription factors that bind promoter/enhancer sequences is another important aspect of understanding gene regulation. The electrophoretic mobility shift assay is a commonly used technique to detect specific DNA-protein interactions (Fig. 12.11). Nuclear proteins are incubated with radioactively labeled oligonucleotides, are subjected to electrophoresis on polyacrylamide gels, and are visualized by autoradiography. DNA bound to protein “shifts,” that is, it migrates more slowly than the unbound radioactive oligonucleotide probe. Bound proteins can be identified by the use of specific antibodies that cause the protein-DNA complex to migrate even more slowly, a so-called supershift. The deoxyribonuclease (DNase) footprinting assay is another assay used to look for transcription factors bound to DNA and to determine precisely which nucleotides are bound by transcription factors that protect them from degradation by DNase treatment.

The chromatin immunoprecipitation (ChIP) assay is a technique that detects protein-DNA interaction in cells (Fig. 12.12).²⁰ In this procedure, nuclear proteins are cross-linked to DNA by formaldehyde. The DNA is sheared and the protein-DNA complexes are immunoprecipitated with antibodies against the proteins that putatively interact with the DNA of interest, so that the DNA bound to these proteins is coprecipitated or captured. The cross-links are reversed, and PCR is used to amplify the regions of genes of interest. These products are then run out on agarose gels. Alternatively, real-time PCR can be employed to detect the DNA that was bound by the immunoprecipitated protein. An extension of these principles allows the identification of virtually all the targets of the investigated DNA-binding protein in different cells under different circumstances. This can be accomplished by labeling the immunoprecipitated DNA fragments and hybridizing them to DNA sequences on a microarray slide (ChIP-on-chip) or by sequencing all of the immunoprecipitated DNA fragments using efficient NGS technologies (ChIP-Seq). When used in combination with other gene expression data, these techniques provide a powerful genomewide screening method to identify target genes of transcription factors.

Recent evidence shows that modification of the histone tail (e.g., acetylation, methylation, phosphorylation) is of considerable importance in regulating chromatin structure and the accessibility of genetic loci to transcription factors.²¹ Alterations of histone modification are very important in explaining transcriptional on-off states. These changes can be assessed using ChIP

Fig. 12.9 With the use of complementary DNA (cDNA) microarrays, the relative expression of tens of thousands of genes can be compared in pairs of samples by extracting RNA from each sample and producing cDNA labeled with one of two different fluorescent dyes (Cy3 or Cy5). The labeled cDNAs are combined and cohybridized to cDNA library probes (polymerase chain reaction [PCR] products) that have been spotted onto the surface of glass microscope slides. The relative intensity of the hybridization signal from the two dyes is a measure of relative gene expression in the two samples.

Fig. 12.10 To determine if a segment of DNA has enhancer/promoter activity, it is cloned upstream of a reporter gene that, when transcribed, will produce the protein encoded by the reporter—such as the luciferase enzyme. The transcription of this gene and hence the production of the protein is measured by an *in-vitro* assay that produces light, with the amount of light produced being proportional to the activation of the promoter. ATP, adenosine 5'-triphosphate.

with antibodies that specifically detect these modifications. The interaction of other transcription factors with promoters and enhancers can also be determined using ChIP in regions with altered histone modifications. Histone modifications are thought to affect the accessibility of genes, and therefore their ability to be acted on by *cis*-acting transcription factors. Accessibility of genes can also be assessed by their ability to be digested with DNase; DNase hypersensitivity is another means of assessing the transcriptional potential of a locus.

Recent work has illustrated that transcriptional regulation can also take place in the context of interactions between disparate genomic loci. Chromosome conformation capture assay (3C assay) is designed to detect these interactions of genomic loci *in vivo*.²² In living cells, two loci that are seemingly far apart on the genome can move into close proximity by “looping out” of the chromosome and sharing DNA-binding proteins. A chemical cross-linker is used to stabilize these interactions. Subsequently, the

captured DNA is digested and ligated to generate a novel junction between the two interacting DNA loci. PCR is then used to detect these novel ligation products, which are indicative of intrachromosomal interactions between a gene locus and a distant enhancer element and even interactions between two loci on different chromosomes. The 3C assay has the potential to uncover coordinated regulation of genes that are not located close together on the genome yet become physically close together during regulatory remodeling of the chromatin.

Many assays of gene regulatory elements are now being performed on a genomewide scale on a myriad of different cell types and the results are being deposited into searchable databases such as the *Encyclopedia of DNA Elements* (ENCODE) (www.nature.com/encode/#/threads)²³ that allow investigators to query the locations of regulatory elements and to design experiments to evaluate their contributions to processes involved in normal as well as diseased states.

ELECTROPHORETIC MOBILITY SHIFT ASSAY

Fig. 12.11 When radiolabeled oligonucleotides are bound by nuclear proteins, their migration in acrylamide gels is retarded or slowed because of their larger molecular weight. This is also referred to as a *shift* in their mobility in the gel. If antibodies (Ab) against the putative DNA-binding proteins are also included, the complex is said to be *supershifted*, and this provides evidence that a particular transcription factor is bound to the oligonucleotide. Chemiluminescent methods can be used to detect biotinylated oligonucleotides to avoid the use of radionuclides.

ANALYSIS OF GENE FUNCTION

The transfer of genes into mammalian cells has been an essential tool to study gene function. These techniques allow examination of the consequence of expression of a new or altered gene and provide us with a great deal of our knowledge about the action of the encoded protein. The cDNAs corresponding to the genes of interest are cloned into expression vectors and are coupled to a strong promoter enabling high expression in cells. For instance, viral promoters are often used to allow high expression in various cell lines. Many different methods are used to transfect these constructs into mammalian cells. These include biochemical methods such as calcium phosphate, diethylaminoethyl-dextran, and liposome-based techniques. Alternatively, for cells that are difficult to transfect by these methods, physical methods such as electroporation and microinjection are used. A third way to transduce genes is by using viral vectors. Developed as tools for gene therapy, these are now widely used in many experiments. The vectors can infect various types of mammalian cells, including cells that are hard to transfect by the other two methods. Adenovirus and retroviruses are representative viruses used for gene transfer. Adenovirus can infect most types of cells and allows transient but high protein expression, whereas retroviruses infect only dividing cells and are characterized by moderate but long-term protein expression.

These methods allow transient expression of genes, which are translated into protein; the effect on cell function can be determined over hours to days. Over time, the cells lose the introduced plasmid construct because of degradation and dilution, but in a few cells the gene is integrated stably into the genome and maintained in offspring cells. These rare cells can be selected by using drug-selection reagents to establish stable transfectants. They typically show lower expression of the gene than with transient expression but are of great use for various experiments.

Recently, new methods have been devised for “knocking down” gene expression. This approach is based on RNA interference (RNAi) and is being heavily employed both in cells in tissue culture and more recently in animal models. For determining the nonredundant function of a particular gene, reducing gene expression has clear advantages over introducing the gene exogenously with plasmid or viral vectors. It is also important for determining whether the functional effects of a treatment depend on a particular gene. RNAi has largely supplanted earlier techniques such as those using

CHROMATIN IMMUNOPRECIPITATION ASSAY

Fig. 12.12 Transcription factors, coactivators, and other DNA-binding proteins can be analyzed by cross-linking these proteins to DNA, followed by DNA shearing and immunoprecipitation with antibodies directed against the proteins of interest. Then protein is digested and the DNA is amplified by polymerase chain reaction with primer pairs for the DNA region of interest. A positive band indicates interaction of the protein with the DNA region (IP-stim) compared with what is seen in the absence of stimulation (IP-unstim). This is normalized to the amount of DNA present initially (input). PCR, polymerase chain reaction.

ribozymes or antisense oligonucleotides for reducing expression of specific genes. RNAi takes advantage of a recently discovered RNA silencing mechanism that is conserved from worms to mammals.²⁴ Double-stranded RNA containing sequences complementary to the targeted gene are cut into 21- to 23-base-pair small interfering RNA (siRNA) fragments using a specialized RNase III enzyme called *Dicer*. These fragments are then incorporated into the RNA-induced silencing complex (RISC), a multiprotein assembly that unwinds the double-stranded siRNA fragments, which bind to complementary sequences in an mRNA molecule. The RISC cleaves the target RNA at a single site in the middle of the complementary sequence, effectively inactivating further translation of the target mRNA. Because a single siRNA in the RISC can inactivate multiple target mRNAs, knockdown of gene expression through this mechanism can be potent (more than 90%) and long lasting (up to 5 days from a single transfection of siRNA duplexes).

The promise of this technique for basic research and therapeutic intervention is beginning to be realized.²⁵ In most higher organisms, including humans and mice, transfection of long double-stranded RNA and even some shorter sequences can activate an antiviral gene response program that induces type I interferon induction and nonspecific RNA degradation by RNase L, so siRNA oligonucleotides shorter than 23 base pairs are used. Synthetic siRNA can be delivered to a variety of cultured cells through conventional transfection methods. More recently, injection of siRNA with a fluid bolus was found to silence gene expression efficiently in mice, and coupling protamine-bound siRNA to a Fab antibody fragment specific for a cell surface molecule was able to target siRNA to specific cell subsets.^{26,27} For long-term silencing of target genes, expression of a “short-hairpin” RNA (shRNA) sequence containing the target siRNA connected by a loop region under the control of an RNA polymerase III promoter is preferred. *Dicer* cleaves the expressed shRNA into siRNA, which is incorporated into the RISC. Viral vectors have been engineered that can drive stable expression of shRNA and silence target RNA molecules in primary cells.^{28,29}

GENETIC MANIPULATION OF MICE

Another way investigators can learn about the function of a gene is to study its *in-vivo* function in a genetic model organism in which its expression and structure can be experimentally manipulated. The mouse is particularly amenable to such studies. Because it is a mammal, its genes and gene functions are very similar to those of humans, but it is possible to manipulate its genome by introducing or overexpressing genes in transgenic mice or by using targeted disruption to destroy a gene in knockout mice.³⁰ Investigators can then study the effects of these genetic alterations in the animals, their tissues, or cells.

Transgenic mice

Transgenic animals are genetically modified animals in which foreign DNA has been experimentally inserted into the transgenic genome. This is accomplished by injecting a DNA construct into the pronucleus of a fertilized oocyte. Blastocysts that develop from these injected oocytes are transferred to pseudopregnant females, in which they develop, to produce potentially transgenic pups (Fig. 12.13). The pups are screened for the presence of the transgene and bred. If the transgene was integrated into the genome of its germline, the animal will then transmit the transgene to the next generation.

The investigator can target expression of the transgene to specific tissues by using tissue-specific promoters or enhancers. The investigator can also control expression of a transgene by using an inducible promoter system such as a tetracycline-regulated system, in which a construct encoding a tetracycline-induced factor under the control of a tissue-specific promoter is introduced in one mouse line and the gene of interest, under the control of a promoter that is controlled by the factor, is introduced into a second line. The tetracycline-induced factor can be either an expression activator or an expression repressor. The lines are then crossbred to generate animals with both genetic alterations, in which expression of the transgene can be controlled in the target tissue by administering or withdrawing tetracycline. Transgenes typically integrate as a tandemly repeated unit within the recipient genome. It is not possible to control the integration site or the number of copies integrated.

Knockout mice

Another way to study the function of a gene is to determine in animals the effect of disrupting the gene so that its product is not produced. Spontaneous mutations that have this effect on genes have provided investigators

Fig. 12.13 Overexpression of DNA constructs in transgenic animals is achieved by injecting a DNA construct (containing the transgene) into the male pronucleus of a fertilized oocyte. The transgene may integrate as a tandem repeat within the recipient genome. Blastocysts are allowed to develop *in vitro* and are then transferred to pseudopregnant female mice. If the transgene has integrated into the genome of the germline, the transgenic offspring (founders) will transmit the transgene to their offspring.

with a great deal of information regarding the function of the affected genes. It is now possible for investigators to experimentally manipulate the genomes of mice by disrupting a gene in pluripotent embryonic stem cells and incorporating those cells into a developing blastocyst (Fig. 12.14).

The technique used to disrupt a gene is to transfect the embryonic stem cells *in vitro* with a DNA construct in which a fragment of the gene sequence has been disrupted by incorporating a selectable marker gene, such as the neomycin resistance marker, that can also be used for positive selection of cells that have integrated the construct. Disruption of the endogenous gene occurs by the process of homologous recombination, whereby homologous sequences flanking the disruption facilitate the exchange of the disrupted gene fragment with the intact fragment of the endogenous gene. The construct may include a coding sequence deletion and/or a premature termination and polyadenylation signal, which, when incorporated within the endogenous gene, blocks its expression. The construct also contains, outside of the gene disruption cassette, a second marker, such as the thymidine kinase marker, that can be used for negative selection to eliminate transfectants in which nonhomologous recombination occurred.

Cells in which homologous recombination occurred are injected into blastocysts and the blastocysts are transferred to foster mothers. Some of the pups produced may be chimeras, in which the genetically altered embryonic stem cells have expanded and contributed to the developing embryo. Through the use of blastocysts and stem cells from strains with different-colored coats, the chimeric pups can be recognized by the contribution of the stem cells to the coat color.

As with transgenic mice, the chimeric offspring are then bred to determine whether the embryonic stem cells contributed to the development of germ cells and will therefore be transmitted to the next generation. Carriers of the chromosome with the disrupted gene can be interbred to produce knockout or gene-targeted mice in which both copies of the gene are disrupted.

A variant of the knockout mouse, the knockin mouse, can be used to trace the temporal and spatial expression patterns of a gene and to study regulation of its expression. In this technique the targeting construct includes a reporter gene, such as the β -galactosidase gene, as well as the

Fig. 12.14 A gene can be effectively deleted from (knocked out of) an animal's genome by disrupting it or deleting an essential domain in embryonic stem cells that can then be transferred to blastocysts, in which they may be incorporated into the germline tissue of the developing embryo. A gene-targeting construct is transfected into embryonic stem (ES) cells, and a disruption cassette replaces a part of the cell's gene by the process of homologous recombination. Because this process is inefficient, a positive selection gene (Neo) is incorporated within the disruption cassette and a negative selection gene (TK) is incorporated outside the cassette to eliminate untransfected cells and transfectants with integration of the targeting construct elsewhere in the genome. Rare cells that have undergone homologous recombination are expanded in culture and injected into blastocysts. Chimeric offspring, into which the targeted embryonic stem cells have been incorporated, can be recognized by the contribution of agouti (brown) targeted (L129) stem cells to the nonagouti (black) coat of the recipient (B6) blastocyst. If the stem cells have contributed to the offspring germline, the offspring will transmit the disrupted gene to its offspring.

selectable marker. The targeted animals produce a chimeric protein in which the reporter gene is fused to a portion of the gene under study. The chimeric gene is expected to be expressed in the same manner as the gene under study. Expression of the chimeric gene can be evaluated by analyzing expression of the reporter gene. This knockin technology can also be used to introduce a disease-associated or other mutation into the gene of interest.

Cre/lox-directed targeted disruption

If disruption of a gene interferes with embryonic development or is lethal, it is difficult to discern its function in knockout mice. Investigators may, however, examine the effect of eliminating the gene's expression from specific tissues or at specific times. These experiments are made possible by the cre/lox recombination system in which lox sites, recognized by the cre recombinase, are inserted in intron sequences flanking an essential portion of the targeted gene. This genetic alteration does not interfere with the gene's

expression. In the presence of the cre recombinase, however, the targeted region is excised from the gene, which leaves a nonfunctional remnant. The cre recombinase can be inserted into the genome as a transgene and an inducible or tissue-specific promoter can direct its expression. In this way, a gene can be disrupted in a specific tissue or at a specific developmental stage by regulating the location and timing of cre expression in the animal.

ANALYSIS OF PROTEINS

The regulation of expression of proteins in cells pertinent to rheumatologic disease is often analyzed. Flow cytometry allows detection of cell surface and intracellular proteins recognized by specific antibodies on a single-cell basis and, with multicolor staining, permits the simultaneous analysis of the expression of several molecules in specific cell populations. Because of the ease of this technique it is commonly employed. To identify the location of a protein of interest within tissues, immunohistochemistry is often used; again, the detection of the protein is dependent on its recognition by specific antibodies. For localization within a cell, electron microscopy or confocal microscopy and immunofluorescence are often employed. Transfection of cells with proteins fused to GFP to be detected under video imaging is a modern technology used to track localization and movement of the molecule in a living cell (see Fig. 12.3).

Immunoblotting or Western blotting is still the most widely used technique to identify protein expression, modification, and interactions with other proteins. In brief, proteins are separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis, transferred to a membrane, and detected by specific antibodies bound to enzymes such as horseradish peroxidase. These antibody-protein complexes are detected by chemiluminescence, autoradiography, or similar methods (Fig. 12.15).

Protein function is regulated by various posttranslational modifications and through dynamic protein-protein interactions; indeed, a paradigm shift in cell signaling has been the understanding of the importance of these interactions. For instance, tyrosine phosphorylation and serine/threonine phosphorylation are major modifications that regulate protein function and assembly of protein complexes. Increasingly, antibodies against phosphorylated forms of various proteins are being made available for the dissection of signal transduction pathways. These antibodies can be used in immunoblotting (see Fig. 12.15) and even in flow cytometry.

Protein-protein interactions can be analyzed by various techniques. Coimmunoprecipitation of one protein with another is a standard technique, but the interactions can be influenced by the detergents used to lyse the cells. Immunoprecipitation reactions require a specific antibody to the protein of interest. Alternatively, using a GST–fusion protein pull-down assay provides good evidence for protein-protein interactions without the need to produce a specific immunoprecipitating antibody. The GST-tagged protein binds with high affinity to glutathione attached to agarose beads. Noninteracting proteins are removed by washing. Proteins that remain bound to the GST-tagged protein can then be assayed by two-dimensional gel electrophoresis or other analytic techniques. A third method for assessing protein-protein interactions is far-Western blotting, in which a labeled recombinant protein is used to “blot” a membrane in which cell lysates have been separated. If the recombinant protein interacts with a cellular protein, the interaction is visualized as a “band.”

Fluorescence resonance energy transfer (FRET) can be used to study protein-protein interactions in living cells as an important complement to strictly biochemical methods. Energy emitted by a fluorophore can be transferred to an acceptor fluorophore causing sensitized emission at a longer wavelength only if the two molecules are in extremely close proximity (<10 nm). Antibodies conjugated to appropriate fluorochromes originally were used to measure protein-protein interactions in this way. More recently, fusion of proteins to fluorescent protein pairs with properties suitable for FRET such as cyan fluorescent protein and yellow fluorescent protein have been used to assess interactions of proteins by microscopy and flow cytometry.³¹ In cell-free systems, protein-protein interactions can be quantitatively measured using surface plasmon resonance.³²

Yeast two-hybrid screening is another method that not only provides a means of detecting interactions between known proteins but also permits the identification of new partners. Most proteins consist of multiple domains with independent functions. Two-hybrid technology takes advantage of these modular functions of a transcription factor protein. Typically, a fusion protein is created in which the DNA-binding domain of the transcription factor is linked to the protein for which interacting partners are sought. This fusion protein, referred to as the “bait,” is expressed in yeast cells. A “prey” library of proteins fused to the transcriptional activation domain of the transcription factor is also expressed in the yeast cells. Cells in which an

Fig. 12.15 In immunoprecipitation, electrophoresis, and Western blotting, cells are typically activated in some way and lysed with detergent-containing buffers. The insoluble material is removed by centrifugation. Staphylococcal protein A bound to agarose beads is incubated with a desired antibody, and this complex is then incubated with cell lysates. The protein or protein complex recognized by the antibody is isolated in this way and then subjected to electrophoresis on polyacrylamide gels, which separates proteins by molecular weight. The proteins can then be electrotransferred to membranes. Modifications of these proteins (e.g., phosphorylation), proteins that coassociate, or the proteins themselves can be detected by incubating the membranes with antibodies (immunoblotting). Ab, antibodies; Mol wt, molecular weight; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; Unstim, unstimulated.

Fig. 12.16 The yeast two-hybrid system is a powerful technique for discovering proteins that interact with a protein of interest. In most transcription factors DNA-binding domains (DBDs) and transcriptional activation domains (TADs) are present in a single protein, which regulates gene transcription through the proximity of the two domains. In the yeast two-hybrid system, these two domains are separated and one fused to the "bait" polypeptide and the other to a library of "prey" polypeptides, which are both expressed in yeast cells. In cells expressing interacting polypeptides, a physical interaction between "bait" and "prey" brings together the transcription factor DBD and TAD domains, facilitating transcription of a reporter gene, in this case β -galactosidase, which turns yeast colonies blue.

interaction of the bait and the prey occurs transcribe the reporter gene. Often the reporter gene encodes β -galactosidase, so that protein-protein interaction is visualized by the blue color of the yeast colonies. If the DNA-binding domain and activation domain are not in proximity, no activation of the reporter occurs (Fig. 12.16).

PROTEOMICS

Proteomics is a term that connotes some of the same issues as genomics. It is defined as the study of the expressed protein complement of the genome and seeks to gain a global and integrated view of changes in protein expression in cells or tissues.^{33,34} Whereas the human genome comprises about 30,000 genes, alternate splicing and different types of modification probably result in at least 100,000 different proteins. Furthermore, proteomics also includes protein-protein interactions and localization, which makes this field far more complex than genomics. It is worth emphasizing in this regard that proteins, and not genes, are the regulators of cell function.

Two-dimensional gel electrophoresis is a multistep procedure that can be used to separate hundreds to thousands of proteins with extremely high resolution. It works by separating proteins by their isoelectric points in the first dimension (isoelectric focusing) and then by their molecular weights in the second dimension (polyacrylamide gel electrophoresis). Using

sophisticated image analysis methods, the proteins from different samples can be compared to identify differences among the samples. Proteins of interest can then be extracted, identified, and further analyzed.

Sequencing of proteins by Edman degradation has been performed since the 1940s, but automation of this technique and microsequencing of proteins transferred to membranes after electrophoresis has greatly improved the ability to identify polypeptides. Mass spectroscopy was devised more than a century ago, but biomolecules are large and polar and are not easily transferred to the gas phase and ionized. However, the development and automation of two methods, electron spray ionization and matrix-assisted laser desorption ionization, has facilitated the application of mass spectroscopy to biology. The identification of polypeptides is also greatly enhanced by the availability of amino acid sequence and peptide mass fingerprinting databases; in this respect, advances in genomics facilitate advances in proteomics.

Like genomics, the field of proteomics has been driven by advances in technology. A variety of new techniques involving microarrays of proteins and tissues are permitting large-scale analysis of protein interactions and localization. Spotting of cell lysates on microarrays is allowing efficient evaluation of pathways; for example, the kinetics of signal transduction pathways has been probed with phosphorylation-specific antibodies.³⁵ Of particular interest to rheumatologists, autoantigen microarrays have been used to profile serum autoantibodies in patients with autoimmune diseases.³⁶

MOLECULAR BIOLOGY: THE NEW PATHOLOGY FOR THE PRACTICING RHEUMATOLOGIST?

Aside from helping the clinician to understand the research papers that appear in the medical literature, what is the utility of the material presented in this chapter? Or to put it another way, what is the likely impact of the molecular biology revolution on the clinical practice of rheumatology?

Rheumatology in the 21st century specializes in a number of disorders that have defied understanding by application of current cellular, biochemical, and immunologic techniques. Whereas systemic lupus erythematosus, rheumatoid arthritis, and osteoarthritis are often viewed as single disease entities, there is great clinical heterogeneity among patients, and it is likely that these conditions are actually syndromes that subsume multiple disorders, each with a distinct pathogenesis, prognosis, and treatment.

Although it is unlikely that molecular biology will be the prism that resolves all of the rheumatic syndromes into their etiologic subsets, the genome revolution and molecular biology techniques provide us with new tools that are already beginning to have an impact. DNA diagnostics for mendelian rheumatic disorders, and gene expression profiling and proteomic analyses for complex rheumatic disorders, are among the molecular techniques that make up what might be regarded as the “new pathology,” and in many cases these approaches promise to redefine the clinical practice of rheumatology. For certain conditions it is already common practice to obtain blood specimens for DNA or RNA extraction for clinically indicated tests. For other conditions, particularly complex rheumatic diseases, molecular studies are still at the level of bench research. However, the practitioner can help to catalyze the potential molecular transformation of rheumatology by participating in studies that often require samples from hundreds or even thousands of patients. The ultimate payoff will be a deeper understanding of and better therapeutic options for rheumatic diseases.

13 Cytokines

■ JOHN J. O'SHEA ■ MASSIMO GADINA ■ RICHARD M. SIEGEL ■ JOSHUA FARBER

- Cytokines are critical factors in host defense and immunoregulation and key players in autoimmunity and inflammation.
- Cytokines belong to different families and bind structurally distinct receptors.
- Mutations and polymorphisms of cytokines, cytokine receptors, and their signaling pathways are associated with a number of human diseases.
- Targeting cytokines themselves or their signal transduction pathways provides many new opportunities for therapy.

INTRODUCTION

Given the extraordinary success of biologic therapies that target cytokines and cytokine receptor signaling, it is hardly necessary to convince readers of the pivotal roles that cytokines play in the pathogenesis of rheumatologic diseases. On the contrary, because of all these exciting developments, rheumatologists are well aware of the criticality of cytokines. Indeed, rheumatologists are increasingly functioning as “applied immunologists,” and other practitioners are looking to rheumatologists for their expertise in the use of these biologic drugs. However, “new” cytokines continue to be identified and new anticytokine therapies continue to be developed. It is also clear that anticytokine therapies are not effective in all patients with a given disease. Furthermore, agents that are efficacious for a given autoimmune disorder are ineffective in others. This suggests differential roles of cytokines in various disorders and perhaps subgroups of patients. For all these reasons it is incumbent on rheumatologists to be experts in the area of cytokine biology. However, this is a daunting task given the sheer number of cytokines and the complexity of their actions. In this chapter our goal is to be reasonably complete but also to provide the reader a conceptual framework for considering the different classes of cytokines. To facilitate the understanding of cytokine action, we provide a few details regarding the signal transduction pathways used by cytokines; however, in an attempt to make the chapter accessible we do not provide an exhaustive discussion of all cytokines and their mechanisms of action.

An additional challenge is that the term *cytokine* does not denote a specific class of structurally or functionally related molecules; on the contrary, many different types of factors produced by immune and nonimmune cells can be included in this category of secreted factors. Terms such as *cytokine*, *lymphokine*, *interleukin*, and *interferon* have been in use for more than 30 years; however, it is probably most reasonable to simply accept the imprecision of the terms and understand that a wide variety of secreted polypeptides can modulate immune and inflammatory responses. Because the problem of intercellular communication is a fundamental one for homeostasis in all multicellular organisms, the boundary between what we think of as cytokines, growth factors, and hormones is also indistinct. For instance, hormones such as growth hormone (GH), prolactin (PRL), erythropoietin (EPO), and leptin are clearly cytokines based on their receptor usage and signaling mechanisms (see below). For this reason it is probably easiest to simply accept that the term “cytokine” is necessarily broad and refers to a subset of factors involved in cell-cell communication. Their actions primarily relate to host defense and regulation of immune and inflammatory cells, but evolutionarily, these factors are homologous to molecules that influence development and coordinate communication between other tissues and organs.

For this reason, in this chapter we classify cytokines not by their function but rather by the type of receptor that they bind. This classification is also useful because it reflects the evolutionary relatedness of cytokines, growth factors, and hormones and emphasizes similarities in modes of signal transduction. Thus, we will broadly discuss the following cytokine categories: interleukin-1 (IL-1), tumor necrosis factor (TNF), type I (hematopoietin) and type II (interferon) proteins, IL-17, receptor tyrosine kinase, transforming growth factor- β (TGF- β), and chemokine receptor families. In the interest of brevity, cytokines that have important immunologic and inflammatory functions will be stressed; only cursory discussion of other cytokines will be provided.

INTERLEUKIN-1 RECEPTOR FAMILY

Ligand and receptor structure

IL-1, a highly pleiotropic factor produced by leukocytes, induces fever, inflammation, and catabolism.¹⁻³ Cytokines of the IL-1 family are evolutionarily ancient and present in echinoderms, tunicates, and annelids, in addition to all species of vertebrates. IL-1 family members form a β -trefoil structure consisting of 12 strands folded into three sheets. These cytokines bind to receptors whose extracellular portions are formed by immunoglobulin domains (typically three) and whose cytoplasmic domains contain a conserved fold known as the TIR domain. TIR domains are also shared with another important class of molecules in host defense known as Toll-like receptors (TLRs). Indeed, TIR is an acronym derived from “Toll, IL-1R, plant Resistance genes,” all of which contain this ancient fold. The known functional receptor complexes are heterodimeric such that the cytokine binds its primary receptor subunit (e.g., the IL-1 receptor [IL-1R]), which then allows recruitment of a second subunit; in the case of IL-1 itself, an “accessory protein” (AcP) is required for initiation of signal transduction.

Family members and their action

The IL-1 family consists of 11 members, whereas the IL-1R family has 10 identified members (Figs. 13.1 and 13.2). Most IL-1 family members lack a signal peptide, the exception being IL-1 receptor antagonist (IL-1Ra, encoded by *IL1RN*—see below). Other than IL-1 α , most IL-1 family members have prodomains, which need to be removed for the cytokine to be biologically active. The prodomains of IL-1 β and IL-18 are removed by caspase-1 cleavage within a protein assembly called the inflammasome (Fig. 13.3). Secretion of active cytokines occurs in concert with their cleavage, although the mechanism of how these cytoplasmic molecules are secreted is not well understood.

The term *inflammasome* refers to a multiprotein assembly whose formation results in the activation of caspase-1 and maturation and secretion of IL-1 β and IL-18.⁴ It has two key components: caspase-1 itself and a recognition/assembly component that is a so-called NOD-like receptor (NLR). Frequently, another protein called ASC (a simple adapter protein containing both pyrin and CARD domains) is required to facilitate assembly. NLR proteins are intracellular pattern recognition receptors that contain three domains: a segment with multiple leucine-rich repeats whose role is to recognize the trigger for activation (whether directly or indirectly remains unclear); a portion called a NACHT domain that leads to adenosine triphosphate (ATP)-dependent dimerization of the NLR after recognition of the trigger; and a protein-protein interaction domain, most commonly either a pyrin or a CARD domain, that recruits caspase-1. The best-studied inflammasome is the so-called NLRP3 inflammasome (see Fig. 13.3). Recognition

Fig. 13.1 The interleukin-1 (IL-1) cytokine family has 11 members that are encoded by a cluster of genes on chromosome 2q. These cytokines are shown schematically, with the prodomains of each cytokines depicted in hatched colors. The putative proteases that process the proforms of these cytokines to mature forms are indicated. Although IL-1 α and, probably, IL-33 have prodomains, removal of the prodomains is not necessary for these cytokines to become active. IL-1 receptor antagonist (IL-1Ra) has a signal peptide.

of the trigger by NLRP3 causes its dimerization, recruitment of ASC via interaction of the pyrin domains of NLRP3 and ASC, and subsequent recruitment of caspase-1 via the CARD domains present in both ASC and caspase-1. Dimerization of caspase-1 on assembly of the inflammasome allows it to become autoactivated by cleavage of the proform to generate active enzyme. The NLRP3 inflammasome is activated by ATP; components of gram-positive bacterial cell walls such as muramyl dipeptide; intracytoplasmic DNA, such as occurs during viral infection; molecules resulting from tissue damage, such as hyaluronin fragments; crystals, including those of uric acid (released from necrotic cells), alum (a commonly used adjuvant), silica and asbestos (environmental contaminants that lead to lung disease), and amyloid- β , a key protein in Alzheimer disease. Cigarette smoke also leads to activation of caspase-1 in mice, but the mechanism is poorly understood. Mutations in NLRP3 result in several hereditary periodic fever syndromes, including familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and neonatal-onset multiorgan inflammatory disease (NOMID; in Europe called chronic infantile neurologic, cutaneous, articular syndrome [CINCA]). NLRP3 is also called cryopyrin, and these disorders have been collectively referred to as cryopyrinopathies.^{5,6} The consequence of disease-causing mutations is excessive release of IL-1 β . Other NLR proteins, including NLRP1, IPAF, NAIP, and AIM2, assemble into their own inflammasomes, which are triggered by other types of stimuli such as gram-negative bacteria and viruses. Mutations in NLRP1 are associated with vitiligo, and several single nucleotide polymorphisms (SNPs) in this gene have been linked to systemic lupus erythematosus (SLE).⁷ Although IL-1 β and IL-18 require cleavage by active caspase-1 to generate their active forms, evidence suggests that secretion of IL-1 α also requires active caspase-1, even though it is not a direct caspase substrate. It is worth noting that although the inflammasome controls the production of IL-1 in monocytes and macrophages, the IL-1 β made by other cells (e.g., neutrophils) is released in its precursor form on cell death and cleaved extracellularly by proteases such as the neutrophil protease PR3.

IL-1 α and IL-1 β

IL-1 α and IL-1 β are the family members with the most widespread influence. Their biologic activities are identical, although they are made by different cells under different influences. The most abundant sources of IL-1 β are monocytes and macrophages. In contrast, IL-1 α is made by many types of cells, but keratinocytes and endothelial cells are particularly rich sources. IL-1 α often remains associated with the plasma membrane of the cell that produces it, whereas IL-1 β is released from cells and diffuses into the surrounding tissue and systemic circulation. The prodomain of IL-1 α also has a nuclear localization signal and is thought to influence the transcription of

Fig. 13.2 The eight members of the interleukin-1 receptor (IL-1R) family, which bind IL-1 family cytokines, are depicted schematically to illustrate the composition of the heterodimeric receptor bound to its cognate ligand. All but the nonsignaling decoy receptor have cytoplasmic TIR (Toll, IL-1R, plant resistance) domains in addition to extracellular immunoglobulin domains. SIGIRR also has an additional 100 to 150 amino acids C-terminal to the TIR domain. IL-1R accessory protein (AcP) is shared by the receptors IL-1R type I, IL-1Rrp2, and IL-33R.

certain genes.⁸ In general, most of the biology of IL-1 can be rationalized by thinking of it as a coordinator of the early host response to infection or tissue injury. Some of the specific effects of IL-1 on different cell types and organs are listed below.

IL-1 is strongly induced by pathogens via stimulation of TLRs on macrophages and other cell types, and it is strongly induced by tissue damage.^{4,9} IL-1 also induces other inflammatory cytokines such as TNF and IL-6, which themselves coordinate aspects of the host response, as well as small-molecule mediators, including nitric oxide and prostaglandins. In addition, IL-1 induces the synthesis of multiple chemokines (see below), particularly those that attract neutrophils to sites of infection or injury. It also induces adhesion molecules on leukocytes and endothelial cells for the same purpose. Simultaneously, IL-1 promotes the release of neutrophils from bone marrow and enhancement of granulopoiesis. Moreover, IL-1 enhances adaptive immune responses by increasing the potency with which antigen is presented by monocyte/macrophages and dendritic cells (DCs). IL-1 is also a key driver of type 17 helper T (Th17) cell differentiation^{10,11} and can also induce Th2 responses. An *IL1B* polymorphism has a large effect on the severity of periodontitis. It is noteworthy that most poxviruses have a homologue of the inhibitory IL-1R type II (see below), thus suggesting that IL-1 plays a role in control of poxvirus infection. Deletion of the IL-1R2 homologue from vaccinia virus leads to greater pathology in mice.

IL-1 is a strong inducer of acute-phase proteins, either directly or via induction of IL-6. IL-1 also promotes cartilage destruction by inducing the production of aggrecanases and collagenases by chondrocytes and by suppressing the synthesis of new collagen and proteoglycan. In addition, it enhances bone resorption, primarily via induction of receptor activator of nuclear factor- κ B ligand (RANKL).

IL-1 is a key mediator of the injury associated with ischemia and reperfusion, and mouse models demonstrate a significant contribution of IL-1 to atherosclerotic lesion formation.

IL-1 is a potent inducer of fever through stimulation of central nervous system (CNS) prostaglandin synthesis. It also causes loss of appetite, enhancement of slow-wave sleep, decrease in energy expenditure, and social withdrawal, a constellation known as "sickness behavior."¹² Inhibition of IL-1 relieves inflammatory and neuropathic pain in rodent models and reverses morphine tolerance. Some of the effects of IL-1 on pain seem to be mediated via induction of matrix metalloproteinases. Finally, IL-1 also seems to play a role in spatial memory in the hippocampus.

There is evidence linking IL-1 to Alzheimer disease and stroke. In many animal models, IL-1 inhibition reduces infarct size, probably by preventing recruitment of neutrophils and thus decreasing bystander tissue damage.¹³ IL-1 is elevated in brains with Alzheimer disease and induces amyloid

Fig. 13.3 Toll-like receptor stimulation by bacterial products induces the production of pro-interleukin-1 β (pro-IL-1 β) and other cytokines. Diverse endogenous and exogenous products ranging from bacterial, viral, and fungal products to adenosine triphosphate, monosodium urate (MSU) crystals, and elevated glucose concentrations lead to activation of a multiprotein complex known as the inflammasome. The inflammasome, in turn, activates caspase-1, which cleaves pro-IL-1 β to form active IL-1 β and IL-18. Patients carrying mutations in *NLRP3* exhibit augmented active caspase-1 and increased IL-1 secretion. ATP, adenosine triphosphate; I κ B, inhibitor of NF- κ B; IL-1 β , interleukin-1 β ; PAMP, pathogen-associated molecular pattern; RANK, receptor activator of nuclear factor- κ B; ROS, reactive oxygen species; TLR, Toll-like receptor; TNF, tumor necrosis factor; TRAF, TNF receptor-associated factor; TRX, thioredoxin; TXNIP, thioredoxin-interacting protein.

precursor protein. In addition, amyloid- β is a trigger for the inflammasome and can induce IL-1.¹⁴ Furthermore, polymorphisms in *IL1A* and *IL1B* alter the risk for development of Alzheimer disease.

Several hematologic malignancies (multiple myeloma, acute myelogenous leukemia, chronic myelogenous leukemia) constitutively secrete IL-1 β , and for early-stage multiple myeloma there is suggestive evidence that IL-1 blockade may reduce the frequency of transition to aggressive disease.

Genetic evidence indicates that polymorphisms in *IL1B* and *IL1RN* affect the risk for and prognosis of gastric, cervical, pancreatic, and breast cancer. The polymorphisms are thought to increase IL-1 β or lower IL-1Ra levels (or both), thereby contributing to cancer risk by promoting inflammation and progression of cancer. These cytokines also induce secretion of IL-8 and vascular endothelial growth factor, which in turn promote angiogenesis.

Negative regulation of IL-1 α and IL-1 β

The actions of IL-1 are tempered by the actions of a critical natural cytokine antagonist, IL-1Ra encoded by the *IL1RN* gene. Mutations in *IL1RN* cause a systemic autoinflammatory disease called deficiency of IL-1Ra (DIRA).¹⁵ A polymorphism in *IL1RN* is also associated with coronary artery disease and restenosis.¹⁶

A recombinant version of IL-1Ra, anakinra, is approved for the treatment of rheumatoid arthritis (RA); however, in most patients the outcome is inferior to that when treated with other biologics such as TNF inhibitors. By contrast, the systemic-onset form of juvenile idiopathic arthritis and its adult counterpart Still's disease respond well to IL-1 inhibition. IL-1 inhibition is highly effective in the treatment of cryopyrinopathies, including NOMID, and has been approved by the Food and Drug Administration (FDA) for these diseases. IL-1 inhibition has also been reported to be effective in treating other autoinflammatory disorders, including Schnitzler syndrome, Behçet disease, hyper-IgD syndrome, PAPA (pyogenic arthritis, pyoderma gangrenosum, and acne) syndrome, and TNF receptor-associated

periodic syndrome (TRAPS). IL-1 inhibition has likewise shown efficacy in the treatment of gout flares.

IL-1 β has recently been found to play a role in more common diseases not formerly considered inflammatory. IL-1 β is made by the pancreas and at low concentration enhances islet beta-cell survival and proliferation and insulin synthesis. At higher concentrations, which can be induced by elevated glucose, IL-1 β has cytotoxic effects on islet beta cells. Amyloid polypeptide accumulates in the islets in diabetes and is also a potent activator of the NLRP3 inflammasome, which may feed back to accelerate diabetogenesis.¹⁷ Early clinical trials also suggest that IL-1 inhibition may be useful in lowering blood glucose and enhancing pancreatic function in type 2 diabetes.¹⁸ Antagonizing IL-1 is also protective against neointima formation following arterial injury in animal models, and IL-1Ra is being studied for the treatment of stroke as well.

Riloncept is a fusion protein containing the extracellular portions of the two IL-1 receptor components IL-1R and AcP, and it has been approved by the FDA for the treatment of cryopyrinopathies. The fully human monoclonal antibody canakinumab is now also used for treatment of the same set of pathologies, and other antibodies are in various stages of clinical development. In addition, canakinumab is being studied as therapy for atherosclerosis.¹⁹

IL-1R type II is a protein homologous to IL-1R type I that binds IL-1 but does not signal. IL-1R type II serves as a decoy receptor to lure IL-1 away from the signaling-competent IL-1R type I. A splice variant of the IL-1 AcP, termed AcPb, negatively regulates IL-1 responses in the CNS.²⁰ Soluble versions of IL-1R type II and AcP also exist and contributes to negative regulation (in the case of soluble AcP, most likely by competition with full-length AcP for binding to surface IL-1/IL-1R complexes). Mice lacking AcPb suffer greater neurodegeneration following the application of a direct inflammatory stimulus to the brain.

Another negative regulator of IL-1 signaling is a cell-surface receptor called SIGIRR. SIGIRR-deficient mice have increased susceptibility to

infection, asthma, and inflammatory bowel disease (IBD) and enhanced signaling by all IL-1 family members that are known agonists (IL-1 α and IL-1 β , IL-18, IL-33, and IL-1F6, IL-1F8, and IL-1F9).²¹ The ST2 receptor may have similar functions.

IL-18

IL-18 is made primarily by DCs and macrophages. Unlike IL-1 β , there is a constitutive pool of pro-IL-18 in producer cells, so regulation of secretion is determined largely by inflammasome activation rather than by transcription. IL-18 acts to promote Th1 cell activation and enhance the cytotoxic activity of CD8⁺ T cells and natural killer (NK) cells by upregulation of FasL.¹ IL-18 is a strong inducer of inflammatory cytokines, especially IFN- γ (its original name was “interferon- γ -inducing factor”). Typically, IL-18 activity is dramatically enhanced by other cytokines, including IL-2, IL-12, IL-15, IL-21, and IL-23. The main reason for the synergy is that IL-18 and the complementing cytokines mutually induce the other's receptors, which are normally expressed at very low levels. In certain circumstances, IL-18 can also lead to induction of Th2 or Th17 cytokines.

IL-18 is elevated in synovium from RA patients and can have a catabolic effect on cartilage. It both induces and is induced by TNF and IL-1. IL-18 is also elevated in IBD (both Crohn's disease and ulcerative colitis). There is likewise a connection with vascular disease. After either stroke or myocardial infarction, IL-18 levels are elevated and correlate with greater extent of atherosclerotic plaque and worse outcome. Individuals carrying an allele in the *IL18* promoter that leads to less IL-18 production have a lower rate of sudden cardiac death. On the other hand, a condition similar to human metabolic syndrome (insulin resistance, hyperglycemia, altered lipid metabolism, obesity, and atherosclerosis) develops in IL-18 or IL-18R knockout mice (or in IL-18bp transgenic animals). Whether this reflects differences between the biology of IL-18 in mice versus humans or simply a level of complexity greater than we currently understand is not yet clear. IL-18R is necessary in mice for the development of inflammation and emphysema following exposure to cigarette smoke, and levels of IL-18 in the lung are elevated in humans with chronic obstructive pulmonary disease (COPD).

The IL-18 receptor (IL-18R α) and its AcP (IL-18R β) are both members of the IL-1R family. An entirely separate gene product, IL-18 binding protein (IL-18bp), acts as a decoy receptor that attenuates the actions of IL-18. It circulates at serum levels typically 20 to 30 times greater than those of IL-18, which is in sufficient excess to block any IL-18 activity. Analogous to IL-1R type II, poxviruses contain a homologue of IL-18bp, thus suggesting a role of IL-18 in controlling viral infection. IL-18bp has been tested in the clinic for psoriasis and RA with limited success. Whether this is due to its relatively short half-life or to IL-18 not playing a key role in these diseases is not clear. Antibodies to both IL-18 and IL-18R are in development for several indications, including IBD (see Table 13.3).

Recent evidence suggests the possibility of other ligands in the IL-18 system. IL-18R-deficient mice are reportedly resistant to experimental autoimmune encephalomyelitis, a model of multiple sclerosis, whereas IL-18 knockout animals are susceptible. On the other hand, IL-18R knockouts have accelerated rejection of transplants and enhanced cytokine production, whereas IL-18 knockouts have the opposite phenotype. Such data suggest the existence of an additional ligand or ligands that act through IL-18R; more work will be required to clarify this picture.

IL-33

IL-33 (previously known as IL-1F11) is abundant in tissues rather than hematopoietic cells.^{1,22} IL-33 promotes Th2 cell activation and cytokine secretion via a receptor formed by the IL-1R family member IL-33R α (previously called ST2 or IL-1RL1) and the same AcP used by IL-1R. In addition, IL-33 promotes survival, maturation, and activation of various cells, including eosinophils, basophils, and mast cells, in which it promotes degranulation, as well as Th2, NK, and NK T cells. IL-13-producing innate lymphoid tissue in the gut is another important target of IL-33. Notably, IL-33-treated basophils have been shown to suppress arthritic inflammation. IL-33 also acts on endothelial and epithelial cells, in which it induces angiogenesis and the production of other cytokines and chemokines. Interestingly, the prodomain of IL-33 can bind DNA. Pro-IL-33 is localized to the cell nucleus and may serve to affect transcription in endothelial and other cells. It is unclear at present whether processing of full-length IL-33 is required for biologic activity. IL-33 does not possess a signal peptide for secretion, and unlike other IL-1 family members, cleavage by caspase-1 can inactivate IL-33.²³ It is thought that IL-33 acts more like an alarmin because necrotic and damaged cells release it.

A soluble form of IL-33R α is generated by alternative splicing and is capable of inhibiting responses to IL-33. Soluble IL-33R α levels are elevated

in acute asthma attacks as opposed to stable asthma and are higher in individuals with stable asthma than in those without asthma. Polymorphisms of IL33RA are associated with the development and severity of asthma and with eosinophilia. Soluble IL-33R α levels are also elevated following myocardial infarction or during destabilized heart failure and correlate with a poor prognosis. Elevated levels of soluble IL-33R α suggest an attempt by the body, usually unsuccessful, to counteract excessive IL-33 signaling in that disease. In addition to strongly inducing typical Th2 cytokines such as IL-4, IL-5, and IL-13, IL-33 can promote typical Th1 responses such as TNF and IFN- γ production. Accordingly, inhibition of the IL-33/IL-33R pathway is beneficial in mouse models of arthritis.

IL-36 members and IL-36 receptor antagonist

IL-36 has three family members: IL-36 α , IL-36 β , and IL-36 γ (formerly designated IL-1F6, IL-1F8, and IL-1F9, respectively). All these cytokines signal via IL-1Rrp2 (HUGO nomenclature, IL-1RL2) and IL-1RAcP.²⁴ Like IL-1, a receptor antagonist exists and is encoded by the gene *IL36RN* (formerly identified as *IL1F5*). These cytokines are highly expressed in the skin and airways and are involved in diseases such as psoriasis. Homozygous loss of *IL36RN* results in pustular psoriasis, whereas inhibition of IL-36 in human psoriatic skin reduces inflammation.

IL-37 and IL-1F10

IL-37 (also known as IL-1F7) exists in several splice variants, of which IL-1F7 β seems to be the most prominent. IL-37 binds to IL-18R α , albeit with lower affinity than IL-18 does. Despite binding to the same receptor and its capacity to complex with IL-18RAcP, IL-37 does not act as a receptor antagonist for IL-18. IL-37 also translocates to the nucleus and binds SMAD3, thereby regulating gene transcription. The biologic function of IL-37 is to negatively regulate excessive inflammatory response and IL-37 transgenic mice are resistant to lipopolysaccharide (LPS)-induced shock.²⁵ IL-1F10 has been claimed to bind to IL-1R. The structure of IL-1F10 suggests that it may be an antagonist as well, but no functional studies have been conducted. IL-37 is the only family member that does not have a murine ortholog.

Signal transduction

IL-1 signaling is initiated by recruitment of the adapter protein MyD88 to the IL-1R/AcP complex via TIR-TIR domain interactions. MyD88 in turn recruits the kinase IRAK-4, which leads to a chain of protein interactions and complexes that include the molecules IRAK-1 or IRAK-2, TRAF6, TAK1, TAB1, and TAB2. This results in activation of the mitogen-activated protein (MAP) kinases extracellular signal-related kinase (ERK), Jun N-terminal kinase (JNK), and p38 and the transcription factors nuclear factor- κ B (NF- κ B), activator protein 1 (AP-1), and related family members. This results in gene induction and mRNA stabilization.²⁶ Phosphatidylinositol-3'-kinase is also activated and contributes via a complementary pathway to the activation of these same MAP kinases and transcription factors. IL-33 and IL-36 likewise activate NF- κ B and MAP kinases.

TUMOR NECROSIS FACTOR RECEPTOR SUPERFAMILY

Ligand and receptor structure

The TNF family of cytokines and their receptors is a structurally related group of molecules that control diverse aspects of cellular function, with a central role in the regulation of both adaptive and innate immune responses (Fig. 13.4; Table 13.1). The seminal observation that antibodies to TNF block endotoxic shock in mice paved the way for investigation of TNF blockade in treating a wide variety of inflammatory conditions, which culminated in the widely successful use of TNF-blocking agents for RA and other rheumatic diseases. These successes validated TNF family cytokines and receptors as therapeutic targets and led to current studies of blocking the action of other members of the TNF superfamily, which are now coming to fruition with a number of agents in late-stage clinical trials (see Table 13.3). With such a large number of cytokines and receptors in this family, translation of knowledge about TNF family cytokines into clinical benefit is only beginning.

All cytokines in the TNF family are synthesized as type II transmembrane proteins. Despite low primary sequence homology, the structures of all TNF family molecules examined to date share a common “ β -jellyroll” structure composed of stacks of β -sheets with variable loops projecting from the core structure that allow specificity of interactions between each TNF family

Fig. 13.4 Receptors that bind cytokines of the tumor necrosis factor (TNF) superfamily are schematically depicted according to their function and the adapter proteins that they bind. Activating receptors induce biologic responses principally through activation of the nuclear factor- κ B (NF- κ B) and mitogen-activated protein kinase signaling pathways initiated by the TNF receptor-associated factor (TRAF) family of adapter proteins. Death-inducing receptors exert their effect via activation of caspase-8 through the adapter protein FADD. Dual signaling receptors can activate either cell death or activation through the adapter protein TRADD, which initially interacts with TRAF family proteins. Under certain circumstances, these receptors can interact with FADD in a delayed manner and induce cell death.

molecule and distinct receptors. The basic structure of TNF family cytokines, whether membrane bound or secreted, is a homotrimer stabilized by noncovalent interactions between residues found in the central core of the TNF homology domain. Lymphotoxin is unique in that it can exist as a heterotrimer composed of one lymphotoxin- α (LT- α) and two LT- β subunits. Cleavage by proteases, typically in the metalloproteinase family, produces soluble versions of most TNF family cytokines that can circulate systemically, although serum levels of TNF family cytokines are often relatively low and not good biomarkers of their activity.

TNF receptors also share basic structural similarities. The extracellular domains of all receptors in the TNF family are composed of variable numbers of cysteine repeat domains (CRDs) forming a rodlike structure stabilized by intrachain disulfide bonds. Receptors can have between one and four CRDs, thus allowing a large degree of diversity. The relationship between ligands and receptors in the TNF superfamily is not always 1:1. Rather, many TNF family cytokines bind more than one receptor, such as TNF interacting with TNFR1 and TNFR2, and a few receptors, such as TACI, bind more than one ligand (APRIL and BAFF). In all ligand-receptor crystal structures examined to date, the TNF cytokine homotrimer is interdigitated within the receptor chains such that each chain of the ligand makes contact with two chains of the receptor at points within the second and third CRDs of the receptor. This hexameric structure allows the relatively low affinity of each ligand chain for receptors to be multiplied by the high valency of interactions to result in nanomolar affinities for most TNF family ligands for their receptors. Interestingly, the N-terminal CRD of receptors contains more than one CRD not bound by ligand, which allows this domain to participate in homotypic receptor-receptor interactions or interactions between TNF receptors and both pathogen-derived and mammalian molecules outside the TNF family. These interactions can serve as mediators for entry of pathogens and also modulate TNFR function.²⁷

TNF family receptor signaling

Unlike some cytokine receptors, TNFRs possess no intrinsic kinase activity, nor do they stably recruit kinases to their cytoplasmic tails. Instead, TNFRs signal through the ordered recruitment of a series of signaling complexes that determine the outcome of engagement by their cognate TNF family cytokine ligands.²⁸ Oligomerization of receptors and downstream signaling proteins is critical for efficient signaling by TNF family receptors, and a number of mechanisms regulate oligomerization of TNF family members.

The majority of TNF family receptors signal through the recruitment of multifunctional adapter proteins termed “TNF receptor-associated factors” [TRAFs]. TRAF proteins bind to short consensus sequences in the intracellular tails of the receptors, with the sequence PXQXT (in which X is any amino acid) preferentially recruiting TRAF proteins 1, 2, 3, and 5 and the sequence QXPXEX preferentially recruiting TRAF6. TRAF proteins are mushroom-shaped homotrimers held together by a coiled-coil “stalk”

domain. Each lobe of the TRAF trimer binds one TRAF interaction motif in the receptor, which results in a hexameric structure that mirrors the TNF-TNFR complex on the outside of the cell. TRAF6 also interacts with TLRs and IL-1R family members, thus explaining the more severe phenotype in individuals with TRAF6 deficiency. A ring finger domain in the N-termini of TRAF2 to TRAF6 allows these proteins to nucleate the assembly of a complex containing the molecules cIAP-1 and cIAP-2, which also contain ring finger domains.²⁹ These ring domains act as E3 ubiquitin ligases and catalyze the addition of K63-linked ubiquitin to many of the components in this signaling complex, including the kinase RIP1 (receptor-interacting protein kinase 1). RIP1 has multiple functions in TNFR1 signaling, such as mediating activation of the NF- κ B and p38 MAP kinase signaling pathways, as well as nonapoptotic cell death. Small molecules have been developed that potently alter signal transduction by inactivating some of these molecules. SMAC mimetics, which mimic a short peptide motif that can bind IAP proteins, induce ubiquitin-dependent degradation of IAPs, a process that potentiates the cell death induced by TNF through TNFR1.^{30,31} Small molecules termed necrostatins bind to RIP1 and inhibit its kinase activity, thereby blocking the ability of RIP1 to induce cell death.³²

Six TNF family receptors (Fas, TNFR1, TRAIL receptors 1 and 2, DR3, and EDAR) are termed “death receptors” because of their ability to trigger programmed cell death. The death domain in the cytoplasmic tail of these receptors confers this ability, although the efficiency of the cell death induced by these receptors depends on the particular adapter proteins recruited to this domain. The death domain forms a globular structure made up of a knot of six α -helices with multiple protein-protein interaction surfaces. Fas and TRAIL receptors recruit the adapter protein FADD through interactions between the death domains present in both proteins. FADD also contains a structurally related domain termed a “death effector domain” (DED) that mediates the recruitment of two proteases, caspase-8 and caspase-10, through tandem DEDs at their N-termini. Caspases are cysteinyl proteases defined by their ability to cleave proteins after aspartate residues based on specific tetrapeptide motifs. Caspases can cleave substrates that initiate inflammation or cell death, and when activated in the signaling complex of TNFRs, caspase-8 and caspase-10 act as initiator caspases in a cascade of protease activation that amplifies the receptor signal and thereby results in efficient death of cells within a few hours after receptor ligation by TNF ligands or agonistic antibodies.³³

Two TNF family receptors, TNFR1 and DR3, contain a death domain but combine both apoptotic and nonapoptotic signaling through recruitment of the adapter protein TRADD. TRADD contains a death domain that mediates recruitment to the death domains of these receptors. However, rather than a DED, TRADD contains a TRAF recruitment sequence in its N-terminus that allows it to recruit TRAF1 and TRAF2 and secondarily cIAP-1, cIAP-2, and RIP to the primary receptor signaling complex. This signaling complex functions similar to that recruited by the non-death domain-containing members of the TNF receptor family. However, after receptor internalization, TRADD dissociates from the receptor and nucleates a second signaling

TABLE 13.1

Selected human tumor necrosis factor family receptors

Common name(s)	Gene symbol	Chromosomal location	Ligands, TNFSF (number)*	Primary adapter protein	Key functions	Disease and therapeutic associations
Lymph node development						
Lymphotoxin- β receptor (LT β R)	TNFRSF3	12p13	LIGHT (14), LT β (3)	TRAF	Lymphoid organ formation	Blocking antibodies have been used in clinical trials for RA
Receptor activator of nuclear factor- κ B (RANK)	TNFRSF11A	18q22.1	RANKL (11)	TRAF	Lymphoid organ formation, dendritic cell costimulation, osteoclast maturation and activation	Blocking anti-RANKL (denosumab) in trial for cancer-associated bone lesions and osteoporosis. Familial osteolytic lesions associated with activating mutations in RANK
Inflammation						
Tumor necrosis factor receptor 1 (TNFR1), p55, CD120A	TNFRSF1A	12p13.2	TNF- α (2), LT β (1)	TRADD	Mediates TNF-induced inflammation by acting on myeloid cells and nonhematopoietic cells such as hepatocytes (and apoptosis in some cells)	Periodic fever syndrome (TRAPS) associated with heterozygous extracellular mutations. Multiple biologics (anti-TNF, TNFR2Fc) effective for RA, spondyloarthritis, inflammatory bowel disease
Lymphocyte costimulation						
Tumor necrosis factor receptor 2 (TNFR2), p75, CD120b	TNFRSF1B	1p36.3-p36.2	TNF- α (2), LT α (1)	TRADD	CD8+ T-cell costimulation	
OX40, CD134	TNFRSF4	1p36	OX40L (4)	TRAF	T-cell costimulation	Anti-OX40L in trials for asthma and other diseases
CD27	TNFRSF7	12p13	CD27L (7)	TRAF	T-cell costimulation	Blocking anti-CD70 in development for autoimmune and inflammatory diseases
CD30	TNFRSF8	1p36	CD30L (8)	TRAF	? Inhibition of CD8+ T-cell effector function	Agonistic anti-CD30 in trials for cancer immunotherapy
4-1BB, CD137	TNFRSF9	1p36	4-1BBL (9)	TRAF	T-cell costimulation	
Herpes virus entry mediator (HVEM)	TNFRSF14	1p36.3-p36.2	LIGHT (14), herpesviruses	TRAF	T-cell costimulation	
Glucocorticoid-induced TNF receptor (GITR)	TNFRSF18	1p36.3	GITRL (18)	TRAF	T-cell costimulation, marker for CD4+CD25+ Tregs, modulates Treg function	
Death receptor 3 (DR3)	TNFRSF25	1p36.2	TL1A (15)	TRADD	T-cell costimulation, secondary T-cell responses	Blocking antibodies effective in mouse models of autoimmune and allergic diseases
CD40	TNFRSF5	20q12-q13.2	CD40L (5)	TRAF	Costimulation and differentiation of B cells and APCs	Hyper-IgM syndrome associated with CD40L or CD40 mutations. Blocking anti-CD40L used for SLE in trials but associated with thrombosis
TACI	TNFRSF13B	17p11.2	APRIL (13), BAFF (13B)	TRAF	May inhibit some of the prosurvival effects of BAFF-R	Mutations in TACI found in $\approx$ 10% of common variable immunodeficiency
BAFF receptor (BAFF-R)	TNFRSF13C	22q13.1-q13.31	BAFF/BlyS (13B)	TRAF		Anti-BAFF/BlyS monoclonal antibody approved for treatment of SLE
Apoptosis						
Fas, CD95	TNFRSF6	10q24.1	FasL (6)	FADD	Apoptosis (chronically stimulated T cells, B cells, dendritic cells, and others)	Autoimmune lymphoproliferative syndrome associated with heterozygous dominant-interfering mutations
Decoy receptor 3	TNFRSF6B	20q13.3	FasL (6), TL1A (15), LIGHT (14)	NA	Soluble decoy receptor for FasL, LIGHT, and TL1A. May have a role in tumor immune evasion	
Death receptor 4 (DR4), TRAIL receptor 1	TNFRSF10A	8p21	TRAIL (10)	FADD	Mediator of dendritic cell and tumor cell apoptosis	TRAIL and agonistic anti-TRAIL-R antibodies in trials for cancer
Death receptor 5 (DR5)	TNFRSF10B	8p22-p21	TRAIL (10)	FADD	Mediator of dendritic cell and tumor cell apoptosis	TRAIL and agonistic anti-TRAIL-R antibodies in trials for cancer
Decoy receptor 1, TRAIL-R3	TNFRSF10C	8p22-p21	TRAIL (10)	NA	GPI-linked decoy receptor, interferes with TRAIL function	
Decoy receptor 2, TRAIL-R4	TNFRSF10D	8p21	TRAIL (10)	NA	Transmembrane decoy receptor, interferes with TRAIL function	

*The number in parentheses refers to the gene symbol number for the TNF family cytokine ligand; for instance, (6) is for TNFSF6.

APCs, antigen-presenting cells; BlyS, B-lymphocyte stimulator; GPI, glycosylphosphatidylinositol; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TRAF, TNF receptor-associated factor; TRAIL, TNF-related apoptosis-inducing ligand; TRAPS, TNF receptor-associated periodic syndrome; Treg, regulatory T cell.

complex containing FADD and caspase-8. Normally, NF- κ B upregulates antiapoptotic molecules such as c-FLIP, which blocks activation of caspase-8 in “complex 2,” but if NF- κ B is blocked, caspase-8 becomes activated and initiates apoptosis.³⁴

TNF can also kill certain cell types even if caspases are inhibited, and it has recently been discovered that an additional pathway of caspase-independent cell death triggered by TNFR1, termed “necroptosis,” exists and is mediated by the kinase activity of RIP1 and RIP3 proteins, which are normally inactivated by caspase-8.³⁵

This was dramatically confirmed in mice in which RIP3 deficiency completely reversed the developmental and lymphocyte activation defects seen with caspase-8 deficiency.³⁶ Small-molecule agents termed necrostatins block RIP kinase activity and are useful for probing the function of this pathway in human cells.³² When cell death occurs after triggering by TNF in the intact animal is still a subject of active investigation.

Although these signaling pathways are common to the receptor superfamily, a large number of regulatory mechanisms allow each TNF family ligand to perform distinct functions that can be quite specialized. Expression of TNF family ligands and receptors is under tight control to produce highly divergent patterns of expression in and outside cells of the immune system. The subcellular localization and cleavage of TNF family ligands are also regulated, and both TNF family ligands and receptors can be cleaved by proteases to produce soluble forms. Genetically related “decoy receptors” can block signaling by binding to a number of ligands and receptors and may themselves initiate “reverse signaling” on engagement with their receptors. Signaling pathways triggered by other cytokines, environmental factors, or genetic programs allow many TNF family receptors to perform more than one function even in the same cell type, for example, switching from inducing cell death to inducing protection from cell death. Not surprisingly, a number of pathogens have evolved proteins that modulate signaling through TNF receptors in a number of interesting ways. Studies of knockout mice and blocking of agonistic agents that affect the function of specific TNF-TNFR interactions, as well as genetic diseases stemming from mutations in genes coding for TNF cytokines and their receptors, have provided a wealth of knowledge about the functions of TNF family cytokines in the intact immune system.

TNF receptor family members and their actions

TNF cytokines can be categorized into subgroups according to their function. The LT- β receptor (LT β R) and RANK share the property of being important for the development of lymphoid structures in the spleen and lymph nodes. Secondary lymphoid structures such as lymph nodes, the white pulp of the spleen, and Peyer patches are induced by the seeding of tissue with specialized bone marrow-derived cells termed lymphoid tissue inducer (LTi) cells. The LT α 1 β 2 heterotrimer produced by LTi cells acts through LT β R on surrounding nonhematopoietic stromal cells to begin this process. In response to lymphotoxin, stromal cells upregulate chemokines and integrins essential for attracting and binding lymphocytes and also secrete RANKL, a TNF family member that in turn can act on LTi cells to enhance expression of lymphotoxin and thereby perpetuate this cycle. This regulatory circuit for lymphoid tissue was discovered through mouse knockout studies, which showed that mice lacking LT- α , LT- β , or LT β R have no lymph nodes, spleen germinal centers, or Peyer patches. Mice lacking RANK or RANKL still have lymph nodes but no spleen DCs or Peyer patches. Lymphotoxin may have distinct functions in the peripheral immune system. LT-LT β R interactions are essential for the ability of DCs to migrate to and proliferate in lymph nodes.^{37,38} Ectopic expression of LT- β promotes “tertiary” lymphoid tissue at sites of inflammation in animal models and a number of disease states.³⁹

TNF acting through TNFR1 is a key amplifier of innate inflammatory responses and septic shock. Local injection of TNF produces acute inflammation, and mice deficient in TNF or TNFR1 are defective in innate immune responses to bacteria but resistant to endotoxic shock. In transgenic mice overexpressing TNF, multiorgan inflammatory pathology develops. However, this pathology of TNF in transgenic mice is independent of T and B cells, thus suggesting that once TNF is produced, its actions are primarily on cells of the innate immune system.⁴⁰ In RA, myeloid cells are the probable source of TNF production, but signals from activated T cells are likely to be important in inducing TNF production within the inflamed joint. Abundant evidence from both mouse and human studies has shown that TNF is a key “master cytokine” in the inflammatory cascade. Patients with RA have elevated levels of TNF- α in their synovial fluid,⁴¹ and TNF levels in synovial fluid correlate with bone erosions.⁴² The efficacy of TNF blockade in reducing the inflammatory activity and erosions in RA has borne out these correlations.

A third group of TNF family members mediates costimulation of lymphocytes and other cells of the immune system. Costimulatory signals synergize with T-cell and B-cell receptor signals on lymphocytes and TLR signals on innate immune cells to enhance the functions of these primary stimuli. Germinal center formation and subsequent B-cell class switching are dependent on interactions between CD40L (CD154) on T cells and CD40 on B cells. CD40L costimulation is also important for DC maturation. CD40L-deficient mice or humans lack germinal centers and have severe defects in B-cell responses (hyper-IgM syndrome). BAFF (also known as B-lymphocyte stimulator [BlyS]) derived from DCs is an additional survival and differentiation factor for germinal center B cells expressing the BAFF receptor. BlyS also binds TACI, which provides additional costimulatory signals for B-cell class switching. About 10% of cases of common variable immunodeficiency have been linked to loss-of-function mutations in TACI.^{43,44} Overexpression of BAFF can induce systemic autoimmunity, and BAFF blockade can inhibit disease in animal autoimmune models. Interestingly, unlike most autoimmune disease models, the autoantibody production mediated by BAFF overexpression is independent of T-cell help.⁴⁵ Another group of TNFRs mediates costimulation for T cells. This large group of receptors includes DR3, 4-1 BB, HVEM, GITR, TNFR2, CD30, OX40, CD27, and their cognate ligands. Mice deficient in these receptors are defective in specific aspects of T-cell responses, and GITR and TNFR2 may play a role in counteracting the suppression mediated by regulatory T (Treg) cells. Mice lacking DR3, OX40, and CD27 are resistant to a number of T cell-dependent autoimmune diseases, and preclinical and clinical development is under way for blocking agents aimed at these targets (see Table 13.3).^{46,47}

TNFRs containing death domains that recruit FADD are particularly efficient in triggering programmed cell death. Fas (also known as CD95) triggers programmed cell death in a number of cell types. For T cells, this occurs when activated cells are restimulated through the antigen receptor, which triggers both FasL gene synthesis and increased sensitivity to the apoptotic effect of Fas ligation, a process known as restimulation-induced cell death. *In vivo*, this cellular suicide mechanism acts to limit the expansion of chronically restimulated T cells, such as those that recognize ubiquitous self-antigens. This pathway can also be experimentally triggered through repetitive doses of antigen, which has been shown to eliminate autoreactive T cells in mouse models of multiple sclerosis. The importance of Fas-FasL interactions in maintaining immunologic self-tolerance is illustrated by the development of systemic autoimmune disease in Fas-deficient mice and humans harboring dominant-negative mutations in Fas associated with autoimmune lymphoproliferative syndrome.⁴⁸ The exquisite sensitivity of chronically activated lymphocytes to Fas-mediated apoptosis may allow strategies to specifically eliminate autoreactive lymphocytes through Fas, although systemic administration of anti-Fas antibodies induces hepatocyte apoptosis and significant liver toxicity in animal models. Receptors for the TNF family cytokine TRAIL mediate efficient cell death in tumor cells, but the role of TRAIL in nontransformed cells seems to be much more restricted. CD8+ cells may express TRAIL and undergo TRAIL-mediated autocrine cell death when CD4+ T-cell help is lacking. However, a nonredundant role for TRAIL in the human immune system has not been clearly identified.

Finally, a group of TNF family receptors mediates the development and function of nonimmune cells. The TNFR RANK is expressed on osteoclasts and is essential for osteoclast function, as shown by the osteopetrosis seen in RANK or RANK ligand deficiency in both mice and humans. In experimental arthritis models, RANKL is expressed by activated CD4+ T cells and is important in causing bone erosions. The TNF family receptor EDAR mediates the formation of teeth and sweat glands, and ectodermal dysplasias characterized by impaired formation of these structures result from loss-of-function mutations in EDAR.

TYPE I AND II CYTOKINE RECEPTORS—HEMATOPOIETIN AND INTERFERON RECEPTORS

Cytokines that bind the class of receptors termed the *type I* or *hematopoietic cytokine receptor superfamily* include hormones such as GH and EPO, colony-stimulating factors (CSFs), and many interleukins. Closely related are the IFNs IFN-related cytokines and IL-10 family cytokines, which bind *type II* receptors. The ligands that bind this receptor superfamily are structurally similar and referred to as the α -helical bundle cytokine family. Structurally, type I family receptors have a conserved Trp-Ser-X-Trp-Ser motif (where X indicates any amino acid) in their extracellular domains, a single transmembrane domain, and divergent cytoplasmic domains; nonetheless, they use the same mode of signal transduction⁴⁹ (Fig. 13.5). Some cytokine receptors, such as the EPO and GH receptors, exist as homodimers. However,

Fig. 13.5 Many cytokines, interleukins, interferons, colony-stimulating factors, and certain hormones bind to type I and II cytokine receptors. These receptors associate with a small family of protein tyrosine kinases known as Janus kinases or JAKs (JAK1, JAK2, JAK3, and TYK2). Cytokine binding activates JAKs, which in turn phosphorylate cytokine receptors so that STAT (signal transducer and activator of transcription) family DNA binding proteins can dock to cytokine receptors and become phosphorylated. Activated STATs dimerize, translocate to the nucleus, and regulate gene expression. A typical heterodimeric receptor is depicted, although some cytokine receptors are homodimers. Mutations in *JAK3* underlie autosomal severe combined immunodeficiency. Mutations in *TYK2* are associated with autosomal recessive hyperimmunoglobulin E syndrome (HIES), whereas mutations in *STAT3* result in autosomal dominant HIES or Job's syndrome. Mutations in *STAT1* are associated atypical mycobacterial infections, and polymorphisms of *STAT4* are linked with susceptibility to systemic lupus erythematosus, rheumatoid arthritis, and Sjögren syndrome.

many cytokines bind receptors that contain two distinct subunits, one of which is often shared by other cytokines. The shared use of receptor subunits is how we will categorize the type I family of receptors (Table 13.2).

Cytokines that use gp130: IL-6 as a prototype

The shared receptor subunit designated glycoprotein 130 (gp130) is a receptor component for a variety of cytokines, including IL-6, IL-11, IL-27, IL-31, leukemia inhibitor factor (LIF), oncostatin M, ciliary neurotrophic factor, and cardiotropin-1. From a rheumatologist's perspective, IL-6 is the most important cytokine in this subfamily.

IL-6R consists of an 80-kDa IL-6 binding protein (α chain) (CD126) and gp130 (CD130). IL-6 is a major proinflammatory cytokine. It induces febrile and acute-phase responses and stimulates the production of fibrinogen, serum amyloid A, haptoglobin, C-reactive protein, and complement proteins. IL-6 decreases the synthesis of albumin and transferrin and induces the production of hepcidin and thereby contributes to pathogenesis of the anemia of chronic disease.⁵⁰ In T cells, IL-6 is an inducer of IL-17 production and Th17 differentiation.⁴⁹ IL-6 is a growth and differentiation factor for B cells and induces immunoglobulin production, including IgA. IL-6 also promotes catabolism, induces insulin resistance, and plays a role in osteoporosis by enhancing osteoclast function.

IL-6 is produced by a wide range of cell types, including T cells, macrophages, adipocytes, and muscle cells. It is induced by other cytokines, including IL-1, TNF, and microbial products. Produced in response to infection, inflammation, and trauma, circulating levels of IL-6 are detectable in serum. Patients with RA, cardiac myxoma, Castleman disease, and other autoimmune diseases have high levels of IL-6 in their sera. Targeting IL-6

with a monoclonal antibody directed against IL-6R (tocilizumab) is efficacious in the treatment of RA, systemic juvenile idiopathic arthritis, and Takayasu arteritis.⁵¹ Other IL-6–blocking antibodies such as siltuximab (a chimeric anti-IL-6) and sirukumab are currently in various phases of clinical experimentation for diseases ranging from cancer to RA to SLE (see Table 13.3). LIF is important for blastocyst implantation and maintenance of stem cell pluripotency in culture. IL-31 is produced by Th2 cells, and overexpression of it results in atopic dermatitis. IL-27 also signals through gp130 but is a heterodimeric cytokine (see below).

Cytokine receptors using the β chain: IL-3, IL-5, and GM-CSF

The cytokines IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) all bind to receptors that share a common β -chain (β_c) receptor subunit (CD131) and also have a ligand-specific α subunit. IL-3 synergizes with other cytokines to stimulate the growth of immature hematopoietic progenitors. In addition, it promotes the survival of macrophages, mast cells, and megakaryocytes. IL-5 promotes the differentiation of eosinophils and thereby contributes to the pathogenesis of allergic disease. GM-CSF promotes myelomonocytic differentiation but also increases the microbicidal activity of myeloid cells. GM-CSF is important for the pathogenesis of Th17 cells in animal models.^{52,53}

Biologics targeting IL-5R (reslizumab) and IL-5 (mepolizumab) itself are being developed for the treatment of asthma, as well as skin and gastrointestinal inflammation (see Table 13.3).

Cytokine receptors using the γ chain: IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21

IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all bind to receptors that share the common γ_c (CD132) in association with a ligand-specific subunit. Mutation of the gene encoding γ_c causes X-linked severe combined immunodeficiency (X-SCID), which is characterized by lack of T cells and NK cells and poorly functioning B cells.⁵⁴

IL-2R consists of three subunits: α (CD25), β (CD122), and γ . T cells, B cells, and other immune cells have inducible expression of the IL-2R α subunit, which creates a high-affinity receptor for IL-2. IL-2 is produced principally by activated T cells and is a prototypic autocrine T-cell growth factor. It augments the cytolytic activity of T and NK cells and induces IFN- γ secretion. IL-2 is also important for CD8+ memory cells. Interestingly, mutation in the genes encoding IL-2 or IL-2R results in autoimmune and lymphoproliferative disease.⁵⁵ This is thought to be due to impaired expression of the transcription factor FoxP3 and impaired development and function of Treg cells. IL-2 also inhibits IL-17 production. IL-2 contributes to class switching in B cells and activates macrophages. IL-2 is approved for the treatment of renal cell carcinoma and has been used to boost CD4+ T-cell counts in patients infected with human immunodeficiency virus (HIV), but its clinical utility is limited by toxicity, including hepatic dysfunction and vascular leak syndrome. Blocking IL-2 with anti-IL-2R α monoclonal antibodies such as daclizumab and basiliximab is approved for use in patients with allograft rejection, but these antibodies are also being considered for the treatment of multiple sclerosis, uveitis, and ulcerative colitis. Polymorphisms of *IL2* and *IL2RA* are associated with a range of autoimmune diseases.^{56,57}

The β_c and γ_c subunits of IL-2R can bind another cytokine, IL-15. IL-15 is critical for NK-cell development and in the generation of memory T cells. IL-15 is produced by hematopoietic and nonhematopoietic cells, and high levels of IL-15 are associated with several autoimmune diseases. Monoclonal anti-IL-15 antibody was studied for RA, but no studies are ongoing at present.

There are two types of IL-4R: one consisting of IL-4R α and γ_c and a second comprising IL-4R α and IL-13R. The former is predominantly expressed on hematopoietic cells. IL-4 promotes an allergic response and differentiation of naive CD4+ T cells into a subset that produces IL-4 and IL-5.⁵⁸ These cells are denoted as Th2 cells. IL-4 also promotes B-cell proliferation and class switching, particularly to IgG1 and IgE. With GM-CSF, IL-4 is also a growth factor for mast cells and basophils. IL-4 inhibits macrophages and the production of proinflammatory cytokines. IL-4 is made by the Th2 subset of CD4+ T cells, NK1.1 CD4+ T cells, basophils, and mast cells. The second receptor is more broadly expressed; consequently, IL-13 has actions on many different types of cells and can promote fibrosis. A fully human antibody to IL-4R (lebrikizumab) is being tested for the treatment of atopic eczema and asthma.⁵⁹

IL-7R consists of IL-7R α (CD127) in association with γ_c . It is expressed on both immature and mature thymocytes. Humans with mutations in

TABLE 13.2
Characteristics of major cytokine families

Receptor subfamily	Cytokine and receptor	Source	Target	Action
Homodimeric	GH	Pituitary, placental	Diverse tissues	Growth, adipocyte differentiation
	PRL	Pituitary, uterus	Mammary epithelium	Growth, differentiation
	EPO	Kidney, liver	Erythroid precursors	Erythroid differentiation
	TPO	Liver, kidney	Committed stem cells and megakaryocytes	Platelet
	Leptin	Adipocytes	Hypothalamus, thyroid	Satiety, controls metabolic rate
	G-CSF	Many tissues, macrophages, endothelium, fibroblasts	Committed progenitors	Differentiation, activates mature granulocytes
gp130-using cytokines	IL-6	Macrophages, fibroblasts, endothelium, epithelium, T cells, other	Liver, B cells, T cells, thymocytes, myeloid cells, osteoclasts	Acute-phase reactants, proliferation, differentiation costimulation
	IL-11	Stromal cells	Hematopoietic stem cells	Proliferation
	CNTF	Schwann cells	Neuronal	Survival
	LIF	Uterus, macrophage, fibroblasts, endothelium, epithelium, T cells	Embryonic stem cells, neurons, hematopoietic cells	Survival
	OSM	Macrophages, fibroblasts, endothelium, epithelium	Myeloid cells, liver, embryonic stem cells	Differentiation, acute-phase induction
β _c -using cytokines	CT-1	T cells, others, myocardium	Myocardium	Growth
	GM-CSF	T cells, macrophages, endothelium, fibroblasts	Immature and committed myelomonocytic progenitors, macrophages, granulocytes, DCs	Growth, differentiation, survival, activation
	IL-3	T cell	Immature hematopoietic progenitors of multiple lineages	Growth, differentiation, survival
γ _c -using cytokines	IL-5	Th2 cells	Eosinophils, B cells	Proliferation, activation
	IL-2	T cells	T, B, NK cells; macrophages	Proliferation, cytotoxicity, IFN-γ secretion, antibody production
	IL-4	Th2 cells, mast cells	T cells, B cells, macrophages	Proliferation, Th2 differentiation, IgG1 and IgE production, inhibition of cell-mediated immunity
	IL-7	Bone marrow, thymic stromal cells, spleen	Thymocytes, T cells, B cells	Growth, differentiation, survival
	IL-9	Th2 cells	T cells, mast cell precursors	Proliferation
	IL-15, IL-21	Many cells	T cells, especially memory cells, NK cells	Proliferation, survival
Heterodimeric	IL-12, IL-23, IL-27, IL-35	Macrophages, B cells	T cells, NK cells	Th differentiation, proliferation, cytotoxicity
Interferons	IFN-α/β	Macrophages, fibroblasts, other	All NK cells	Antiviral, antiproliferative, increased MHC class I activation
	IFN-γ	Th1 cells, NK cells	Macrophages, endothelium, NK cells	Activation, increased MHC class II expression, increased antigen presentation
IL-10 family	IL-10, IL-22	Th2 cells, other cells	Macrophages	Decreased MHC class II expression, decreased antigen presentation

CNTF, ciliary neurotrophic factor; CT-1, cordiotropin-1; DCs, dendritic cells; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GH, growth hormone; GM-CSF, granulocyte-macrophage colony-stimulating factor; gp130, glycoprotein 130; IFN, interferon; IL-6, interleukin-6; LIF, leukemia inhibitor factor; MHC, major histocompatibility complex; NK, natural killer; OSM, oncostatin M; PRL, prolactin; Th2, type 2 helper T cell; TPO, thrombopoietin.

IL-7Rα have SCID characterized by the absence of T (T-B+ SCID).⁶⁰ IL-7 is also important for memory T cells. It is produced by a wide variety of cells, including marrow and thymic stromal cells. TSLP is an IL-7–like cytokine expressed by epithelial cells and keratinocytes. Its receptor is composed of TSLPR and IL-7Rα, which is expressed primarily on monocytes and DCs, as well as on B cells. TSLP seems to promote Th2 differentiation through its effects on DCs. Polymorphisms of *IL7R* are associated with multiple sclerosis.⁶¹

IL-9 synergizes with stem cell factor (SCF) to promote the growth and differentiation of mast cells, potentiates the IgE production induced by IL-4, and promotes mucus production. IL-9 is also secreted by eosinophils and activated Th2 cells. A new subset of helper T cells designated Th9 cells has been identified that selectively produces this cytokine.⁶² These cells also secrete IL-10 but augment inflammatory responses. Conversely, IL-9 inhibits Th1 cytokine production. Anti-IL-9 monoclonal antibody (enokizumab) is being tested for the treatment of asthma.

IL-21 binds to a receptor composed of the IL-21 α and γ chains. IL-21 is produced by Th17 cells and by follicular helper T (T_{fh}) cells. IL-21, along with IL-6 and other cytokines, promotes T_{fh} differentiation. T_{fh} cells are localized to B-cell follicles and promote immunoglobulin class switching and B-cell differentiation into memory cells and plasma cells. IL-21 can also

promote Th17 differentiation. It is highly expressed in SLE and models of autoimmunity.⁶³

Homodimeric receptors

A large number of cytokines that use homodimeric receptors are classic hormones, including the factors GH, PRL, leptin, and granulocyte colony-stimulating factor (G-CSF). EPO is included in this subfamily and is required for erythrocyte growth and development. Similarly, thrombopoietin is required for megakaryocytic development. These recombinant cytokines are commonly used drugs.

Heterodimeric cytokines

A small number of cytokines are structural distinct in that they are heterodimers; this family includes IL-12, IL-23, IL-27, and IL-35. These heterodimers consist of one subunit that is homologous to other cytokines and another that is homologous to cytokine receptors. For instance, IL-12 has two subunits, p35 and p40. IL-12 p35 shares homology with cytokines, whereas p40 resembles IL-6R. Thus, these cytokines can be thought of as a preformed ligand/receptor complex. IL-12R consists of two subunits, IL-12Rβ1 and

IL-12R β 2, which are present on T and NK cells. A major action of IL-12 is to promote the differentiation of naive helper T cells to the Th1 subset, which makes IFN- γ . Humans with IL-12R mutations have blunted immune responses and are susceptible to infections by intracellular pathogens. In contrast, IL-23 is composed of p19 and IL-12 p40, and its receptor consists of IL-12R β 1 paired with IL-23R.⁶⁴ This receptor is expressed on activated T and NK T cells, and IL-23 promotes the production of IL-17. As a result, IL-23 is very important for host defense against extracellular bacteria and in the pathogenesis of autoimmune and autoinflammatory disorders.⁶⁵ DCs and macrophages produce IL-12 and IL-23 in response to occupancy of pattern recognition receptors. Polymorphisms of the gene encoding IL-23R are associated with IBD, spondyloarthritis, and multiple sclerosis.⁶⁶ The human monoclonal antibody ustekinumab targets the p40 subunit shared by IL-12 and IL-23. In the clinic this drug has proved to be very effective for the treatment of psoriasis and psoriatic arthritis. It is also efficacious in the treatment of IBD but, interestingly, not multiple sclerosis.⁶⁷⁻⁶⁹

IL-27 is composed of two subunits designated EB13 and p28. It signals through a receptor composed of gp130 and WSX-1/TCCR (T-cell cytokine receptor), which is expressed on naive CD4+ T cells. IL-27 can promote Th1 differentiation and induce IL-21 production, but it also has critical antiinflammatory properties. An important effect of IL-27 is to induce production of the antiinflammatory cytokine IL-10.⁷⁰ IL-35 is another dimeric cytokine consisting of IL-12 p35 and EB13.⁷¹ It is produced by Treg cells, and Treg cells are also a target of IL-35 activity because it induces the proliferation and production of IL-10 by such cells. The receptors for IL-35 are homodimers and heterodimers of gp130 and IL-12R β 2.⁷² Administration of recombinant IL-35 reduces the incidence of arthritis in mouse models.

Interferons

The type I IFNs include IFN- β , IFN- ω , and IFN- β ; however, there are at least 14 separate IFN- α genes. All these ligands bind to a heterodimeric receptor composed of two subunit, IFNAR1 and IFNAR2, and therefore have similar actions. Discovered more than 50 years ago, the major effect of type I IFNs is their antiviral action: inhibition of viral replication, protein translation, and cellular proliferation.⁷³ They also upregulate major histocompatibility complex (MHC) class I expression, downregulate MHC class II expression, and increase the cytolytic activity of NK cells.

Type I IFNs are produced ubiquitously and induced by viral and bacterial infections. A subset of DCs, plasmacytoid DCs, produce especially high levels of IFNs. Type I IFN is used clinically for the treatment of viral hepatitis and leukemia. IFN- β has also been used as an immunosuppressant in the treatment of multiple sclerosis. The IFN signature of changes in gene expression is now a well-recognized characteristic of SLE, and therapeutic use of type I IFNs has additionally been associated with the appearance of antinuclear antibodies and the development or exacerbation of autoimmune disease. Therapeutic blockade of type I IFNs (e.g., rontalizumab and sifalimumab) is currently being tested in patients with SLE, dermatomyositis, and polymyositis (see Table 13.3). Curiously, though, in other settings such as multiple sclerosis, administration of IFN- β is immunosuppressive. Exactly how IFNs can promote and inhibit autoimmunity is far from clear.

IFN- γ , also known as type II IFN, binds to a dimeric receptor composed of IFN γ R α and IFN γ R β subunits. IFN- γ is a major activator of macrophages, and it enhances their ability to kill microorganisms. It induces nitric oxide and upregulates MHC class II expression. IFN- γ acts on CD4+ T cells to promote Th1 differentiation and inhibit Th2 differentiation. It augments NK and CD8+ T-cell cytolytic activity. In B cells, it promotes switching to IgG2a and IgG3 and inhibits switching to IgG1 and IgE.

IFN- γ is produced primarily by Th1 and NK cells. Humans with mutations in IFN γ R subunits are also susceptible to *Mycobacterium* and *Salmonella* infections.⁷³ Conversely, IFN- γ has been used to treat patients with immunodeficiencies (e.g., chronic granulomatous disease) and disseminated mycobacterial infections. Clinical use of IFN- γ can be associated with the production of autoantibodies and a lupuslike syndrome. A monoclonal anti-IFN- γ antibody, fontolizumab, was tested for RA, but the trial was terminated. Other IFN-like cytokines, including IL-28A, IL-28B, and IL-29 (also designated IFN λ 1, IFN λ 2, and IFN λ 3), have been identified. These molecules appear to be involved in antiviral responses, but their exact functions are less well understood than those of other IFNs.

IL-10 family

IL-10 is a critical immunosuppressive cytokine; mice lacking this cytokine have autoimmunity and IBD. Its receptor consists of two chains, IL-10R1 and IL-10R2, and IL-10 inhibits the production of inflammatory cytokines

and decreases the expression of MHC class II, adhesion molecules, and costimulatory molecules. IL-10 is produced by a wide variety of immune cells and is induced by IL-6, LPS, and TNF. Levels of IL-10 are present in the blood of patients with septic shock and other inflammatory and immune disorders.

IL-22 binds to IL-10R2, but it also uses another receptor, termed IL-22R. It is produced by Th17 cells but is likewise made by nonconventional NK cells (NKp44/46+). It is important for epithelial barrier function and host defense in the gut but also has critical antiinflammatory effects. Moreover, it is involved in the pathogenesis of psoriasis. Other IL-10–related cytokines include IL-19, IL-20, IL-24, and IL-26, but their biologic actions are less well understood and they exhibit considerable sharing of receptors.⁷⁴

Signaling by type I/II cytokine receptors

Type I and II receptors have no intrinsic enzymatic activity but instead are associated with Janus kinases (JAKs), which play a pivotal role in signaling via this family of cytokine receptors (see Chapter 14).⁴⁹ There are four JAKs, JAK1, JAK2, JAK3, and TYK2, and they bind to different cytokine receptor chains. Ligand binding activates the JAKs, and they in turn phosphorylate cytokine receptor subunits on tyrosine residues, thereby allowing the recruitment of signaling molecules. Deficiency of JAK3 results in autosomal recessive SCID with failure to signal by γ_c cytokines, whereas mutation of TYK2 is associated with an autosomal recessive form of hyperimmunoglobulin E syndrome (HIES). JAK2 is important for many cytokines, including EPO, and mutation of JAK2 underlies most cases of polycythemia vera. Polymorphisms of TYK2 and JAK2 are also associated with autoimmune disease. JAK inhibitors, or jakinibs, represent a new class of immunomodulatory drugs.⁷⁵ One JAK inhibitor, tofacitinib, is approved for the treatment of RA in patients with inadequate responses to methotrexate. Tofacitinib is also being studied for IBD and psoriasis. Other jakinibs are in various levels of development and testing (see Table 13.3).⁷⁶

An important class of molecules activated by JAKs is the signal transducer and activator of transcription (STAT) family of DNA binding proteins. Seven mammalian STATs are recognized: STAT1, STAT2, STAT3, STAT4, STAT5a, STAT5b, and STAT6. Mutations in STAT1, which is activated by IFNs, results in increased susceptibility to *Salmonella* and *Mycobacterium* infections, as well as autosomal dominant chronic mucocutaneous candidiasis.^{73,77} STAT3 is activated by a variety of cytokines, and mutations in this gene result in an autosomal dominant primary immunodeficiency syndrome referred to as AD-HIES or Job syndrome.⁷⁸ An important aspect of the susceptibility of these patients to infection is the failure to generate Th17 cells. Conversely, polymorphisms of STAT3 are associated with IBD. STAT4 is activated by IL-12, and type I interferons have critical functions in Th1 differentiation; polymorphisms of STAT4 are associated with RA, SLE, and Sjögren syndrome.⁷⁹ STAT6 is activated by IL-4 and IL-13 and is important in Th2-mediated responses. STAT5a and STAT5b are homologous and have overlapping functions. STAT5 is important for the expression of FoxP3, and mice lacking these transcription factors have impaired Treg cell development and autoimmunity. Mutations in STAT5B are associated with impaired responses to GH, immunodeficiency, and autoimmunity.⁷⁶

INTERLEUKIN-17 RECEPTORS

The IL-17R family comprises five receptors, IL-17RA through IL-17RE, which are ubiquitously broadly expressed.⁶⁵ IL-17 family ligands include IL-17A to IL-17F; IL-17E is also called IL-25.

IL-17 (IL-17A) and IL-17F are produced by a subset of CD4+ T cells referred to as Th17 cells.⁸⁰ These cells can be differentiated in different ways by using cocktails of cytokines that include IL-1 β , IL-6, IL-21, and TGF- β . IL-23 appears to have a critical role in regulating the biologic activity of these cells. IL-17 cytokines are also produced by $\gamma\delta$ T cells, CD8+ T cells, invariant NK cells, and LT α cells.⁸¹ IL-17A is important for host defense against gram-negative extracellular bacteria such as *Klebsiella pneumoniae*.⁶⁵ Additionally, though, abundant data point to pathogenic roles of IL-17A in models of immune-mediated disease and in human autoimmune disorders. IL-17A and IL-17F evoke inflammation by inducing the production of G-CSF, GM-CSF, and chemokines. Accordingly, they are important regulators of stress granulopoiesis and recruitment of myeloid cells to sites of inflammation. Given the importance of IL-17 in immune-mediated disease, targeting of IL-17 has attracted a great deal of attention. Ixekizumab and secukinumab, which bind IL-17A, as well as brodalumab, an antagonist of IL-17RA, appear to be effective in psoriasis and are being considered for other disorders, including uveitis, Crohn disease, RA, psoriatic arthritis, and

ankylosing spondylitis (see Table 13.3). Autoantibodies can be produced against IL-17 and other cytokines critical for host defense⁸² and result in increased susceptibility to infection.

IL-17E (IL-25) is produced by Th2 cells and mast cells and evokes an inflammatory response characterized by overproduction of Th2 cytokines, mucus production, epithelial cell hyperplasia, and eosinophilia. IL-25 is essential for elimination of helminthic parasites. IL-17B, IL-17C, and IL-17D are less well studied.

The IL-17 family receptors include a group of five subunits, IL-17RA to IL-17RE. All have single transmembrane domains with large cytoplasmic tails that contain a motif similar to the TIR domain of TLRs. This is referred to as a SEFIR domain. The adapter molecule Act-1 also has a SEFIR domain and binds to IL-17R through a homotypic interaction. In addition, IL-17RA contains a C/EBP β activation domain. Another adapter molecule used by TNF family cytokines, TRAF6, also contributes to IL-17 signaling. Engagement of IL-17R activates MAP kinases and NF- κ B, as well as the generation of C/EBP β and C/EBP δ dimers via the activation of GSK3 β . IL-17 acts synergistically with TNF.

TRANSFORMING GROWTH FACTOR- β RECEPTOR FAMILY CYTOKINES

The TGF- β family consists of more than 40 cytokines, including TGF- β 1, TGF- β 2, and TGF- β 3, bone morphogenic proteins, activins, inhibins, and müllerian inhibiting substance; only TGF- β 1 is discussed here. The receptor for TGF- β 1 is a dimer consisting of two receptor serine-threonine kinases, TGF β R1 and TGF β R2. Functionally, TGF- β inhibits many aspects of lymphocyte function, including T-cell proliferation and cytokine production. TGF- β 1 also induces FoxP3 and promotes differentiation of Treg cells. Accordingly, mice lacking this cytokine or its receptor have overwhelming autoimmune disease. The TGF- β cytokines are expressed as biologically inactive disulfide-linked dimers that require processing to be active. The enzyme furin cleaves TGF- β , and deficiency of furin is associated with systemic autoimmunity. Paradoxically, TGF- β 1 acting with IL-6 induces the proinflammatory cytokine IL-17.⁸¹ Thus, TGF- β 1 has both proinflammatory and antiinflammatory activity. TGF- β cytokines also induce fibrosis and may participate in the pathogenesis of diseases such as systemic sclerosis.

Signaling

On ligand binding, the type II receptor phosphorylates the type I receptor, which allows recruitment of the SMAD family transcription factors SMAD2 and SMAD3. Activated SMADs associate with SMAD4, and the complex translocates to the nucleus to bind promoters of TGF- β -responsive genes. SMADs interact with a variety of other transcription factors, transcriptional coactivators, and transcriptional corepressors. TGF- β also signals via TAK1 (TGF- β -associated kinase-1), which associates with TAB1 (TAK1-associated binding protein), and activates members of the MAP kinase family.

RECEPTOR TYROSINE KINASES

Classic growth factors such as the epidermal growth factor and insulin signal through receptor that are themselves tyrosine kinases and hence are designated receptor tyrosine kinases. Most of the ligands that use these receptors are not classified as cytokines, but some are, including CSF-1 (macrophage colony-stimulating factor [M-CSF]), SCF (c-kit ligand or steel factor), FMS-like tyrosine kinase 3 ligand (FLT3L), and platelet-derived growth factor (PDGF). Structurally, SCF and CSF-1 are similar to the four α -helical cytokines, thus suggesting a common evolutionary ancestor for both groups of cytokines. SCF is widely expressed during embryogenesis and makes stem cells responsive to other CSFs. It is also important for the differentiation of mast cells. FLT3L acts with SCF to induce proliferation of hematopoietic precursors. It is likewise important for the generation of DCs. Gain-of-function mutations in c-kit cause systemic mastocytosis, and mutations resulting in fusion of the *PDGFRA* and *FIP1L1* genes underlie hypereosinophilic syndrome. CSF-1 supports the survival and differentiation of monocytic cells. IL-32 is distinct from CSF-1 but binds the same receptor.

CHEMOKINES

As a collection of functionally integrated but anatomically dispersed populations of hematopoietic cells dedicated to defense of the host, the immune system, like any army, depends absolutely on communication and mobility.

Within the immune system, cell migration is necessary during development, homeostasis, and response to pathogen challenge. Several classes of molecules regulate this migration, among them chemoattractants and their receptors. The largest gene family of chemoattractants is the chemokines (chemotactic cytokines), and it contains more than 40 members.⁸³

Ligand and receptor structure

All the chemokines are small, secreted proteins (molecular weight of approximately 10 kDa), with the exceptions of CX₃CL1 and CXCL16, which are membrane anchored through transmembrane domains, in addition to having soluble forms generated through proteolytic cleavage. Although chemokines are secreted, they become immobilized by binding to glycosaminoglycans on cell surfaces and extracellular matrix, and it is generally thought that the immobilized chemokines are the active forms, sometimes forming fixed gradients for chemotaxis.

Chemokines can be divided on the basis of the arrangement of conserved cysteine residues near the N-termini into CXC, CC, CX₃C, and XC subfamilies, where X is a variable amino acid. The CX₃C and XC subfamilies contain only one and two members, respectively, with all the rest being CXC or CC chemokines. The systematic names for chemokines consist of the subfamily, followed by “L” for ligand and a number, which generally reflects the order of discovery.

Chemokines signal through seven-transmembrane domain G protein-coupled receptors (GPCRs), 19 of which have been identified in humans. The superfamily of GPCRs contains almost 1000 members in humans, including the subfamilies of odorant and taste receptors and receptors for light, neurotransmitters, and catecholamines. Because GPCRs have been successfully targeted by a large number of small-molecule drugs, studies of the chemokine system have always maintained a view to potential therapeutic applications. For further details on chemokines, including discussion of CXCL12, CXCR4, CCR7 and CCR5, see the online supplement.

Signaling

GPCRs are defined by the central feature of their signaling pathway, namely, activation of heterotrimeric G proteins through conformational changes in their cytoplasmic domains that are induced by binding of ligands to their extracellular domains. Heterotrimeric G proteins contain 1 each of 23 different α , 5 β , and 10 γ subunits. Receptor-mediated G-protein activation leads to replacement of G α subunit-bound guanosine diphosphate (GDP) with guanosine triphosphate (GTP) and dissociation of the trimer into G α -GTP and a $\beta\gamma$ dimer. For chemokine receptor-mediated processes (e.g., chemotaxis), the $\beta\gamma$ dimer is the critical activator of downstream signaling proteins, such as phosphatidylinositol-3'-kinase, which ultimately leads to actin polymerization and the formation of lamellipodia at the leading edge and actin-myosin-mediated retraction of the uropod at the trailing edge.¹⁰⁶ The 23 G α subunits fall within four subfamilies, and heterotrimers are grouped similarly, based on their G α components, into the G_i, G_s, G_q, and G_{12/13} subfamilies. All chemokine receptors signal through G_i proteins, which by using pertussis toxin—the specific inhibitor of G_{i/o} subunits—can be shown to be essential for chemotaxis. G_{12/13} proteins have also been implicated in chemotaxis, with activated G_i and G_{12/13} proteins being responsible for creating, respectively, the front-specific and back-specific components of migrating cells.¹⁰⁷

Control of chemokine receptor function also requires limiting the duration of the activating signals, which is achieved through a number of mechanisms. G α subunits have intrinsic GTPase activity, and once GTP is hydrolyzed to GDP, the G α -GDP reassociates with a $\beta\gamma$ dimer to form the “resting” heterotrimer. G α -GTPase activity can be accelerated by GTPase-activating proteins (GAPs), which for the G α subunits are members of the RGS family of proteins.¹⁰⁶ The chemokine receptors themselves are typically desensitized after chemokine binding through the activity of G protein-coupled receptor kinases (GRKs), which phosphorylate serine/threonine residues in the receptors' C-terminal tails. Receptor phosphorylation leads to the recruitment of arrestin proteins, which is typically followed by receptor internalization leading to degradation or recycling of receptors to the cell surface. At the same time that they serve to limit receptor-mediated activation of G proteins, arrestins can also activate additional, G protein-independent signaling pathways.¹⁰⁸

Sphingosine-1-phosphate

Another key pair of proteins that are not within the chemokine system but have an important related function in lymphocyte trafficking through lymphoid organs are sphingosine-1-phosphate and one of its receptors, the

An important aspect of receptor-ligand relationships in the chemokine system is promiscuity. One ligand can often bind to more than a single receptor, and receptors generally bind to more than a single ligand. Nonetheless, a given receptor will bind chemokines only within a single subfamily, a feature that underlies the receptor nomenclature: CXCR1 to CXCR7 and CCR1 to CCR10 are receptors for CXC and the CC chemokines, respectively, whereas CX₃CR1 and XCR1 are the receptors for CX₃CL1 and XCL1, respectively. In addition to receptor-ligand promiscuity, an additional level of complexity is seen in the patterns of expression of receptors on leukocytes. Although some receptors are dominant in controlling migration of a given cell type, such as CXCR1 and CXCR2 on neutrophils and CCR3 on eosinophils, all leukocytes express multiple chemokine receptors, so within a given context, blocking a single receptor may not prevent recruitment of the cells. Finally, a number of chemokine receptor–like proteins, although they bind chemokines, do not produce intracellular signals. These so-called atypical chemokine receptors seems to function as chemokine scavengers and can have critical roles in establishing the spatial distribution of chemokines in tissue.⁸⁴

As discussed below, a number of clinical trials of antagonists of individual chemokine receptors as antiinflammatory drugs have not been encouraging and led to the proposal that “promiscuous” drugs that target multiple receptors need to be developed so that the system’s redundancy can be overcome.⁸⁵ On the other hand, clinical investigations focused on the chemokine system are still in their early stages, particularly given the complexity of the system and the limited understanding of how the system is functioning in disease. It may therefore be premature to abandon the goal of using single-receptor antagonists to treat inflammatory disorders.

It is important to note that chemokines/chemokine receptors are only one component of the molecular system important for leukocyte trafficking, a critical step of which is movement of cells out of postcapillary venules into tissue. Such transendothelial migration has been described in studies using a multistep model of selectin-mediated rolling, followed by activation of a chemoattractant GPCR, integrin-mediated firm arrest, and diapedesis.⁸⁶ Selectins and their ligands are expressed on both leukocytes and endothelial cells, whereas the relevant chemoattractant GPCRs and integrins are expressed on leukocytes with their ligands on endothelial cells—in the case of chemokines, immobilized on the endothelial cell surface. It is generally thought that chemokines also form gradients within tissues up which cells move, and there is some direct evidence for such gradients.⁸⁷

CXCL12 and CXCR4 and immune cell development

A role for chemokines in leukocyte development has best been shown in studies of CXCL12 and its receptor CXCR4, which are unusual in the chemokine system in being highly conserved during evolution.⁸⁸ Cxcl12^{−/−} mice show defective B lymphopoiesis and bone marrow myeloopoiesis.⁸⁹ This presumably reflects the role of CXCL12/CXCR4 in homing and retention of hematopoietic stem cells to appropriate niches within bone marrow.⁹⁰ A CXCR4 antagonist, plerixafor (AMD3100/Mozobil), is now being used clinically to enhance stem cell mobilization for subsequent autologous transplantation in individuals with non-Hodgkin lymphoma or multiple myeloma.

CCR7 and CCR5 and immune anatomy

Roles for chemokines in immune system anatomy and homeostasis are evident in the functions of CCL19 and CCL21 and their receptor CCR7 and in the function of CXCL13 and its receptor CXCR5. CCL19 and CCL21 are expressed on high endothelial venules and in the T-cell zones in lymph nodes and other secondary lymphoid organs, and these chemokines are required for trafficking and positioning of T cells and DCs within secondary lymphoid organs.^{91–93} The counterparts for B cells are CXCL13, which is expressed in B-cell follicles,⁹³ and CXCR5, which is expressed on B cells and on effector/memory T cells that traffic to B-cell follicles, so-called T_{fh}, or follicular helper cells.⁶² Because B cells are critical for the formation of lymphoid organs during development, lymph nodes and Peyer patches in mice lacking CXCR5 are absent or rudimentary.⁹⁴

Other family members

The majority of chemokines and their receptors function in recruiting leukocytes, including myeloid cells, NK cells, and activated/memory lymphocytes, into inflamed tissue sites. Most of these chemokines/receptors do not have roles restricted to specific organs or tissues, but there are exceptions. The chemokine best documented as being specific for a peripheral tissue is CCL25, the ligand for CCR9A/B, which (in addition to a role on thymocytes) has a role in recruiting lymphocytes specifically to the gut and preferentially to the small intestine. Together with the gut-associated integrin $\alpha_4\beta_7$, CCR9 is induced on T cells specifically by DCs from Peyer patches, thereby imprinting activated/memory T cells to home to the bowel.⁹⁵ As a result of these

and related findings, a CCR9 antagonist is currently being investigated in phase 3 trials for the treatment of Crohn disease (ClinicalTrials.gov identifiers NCT01318993 and NCT01316939) following preliminary reports of the drug’s effectiveness in treating this disorder in a phase 2 study.

The major chemokine receptors for recruitment of the principal populations of myeloid “effector” cells are CXCR1 and CXCR2 on neutrophils and CCR2 on monocytes/macrophages. A number of agents have been developed to block CXCR1 or CXCR2 and have been evaluated in clinical trials for diseases with neutrophil-mediated tissue damage, such as COPD, cystic fibrosis, ulcerative colitis, and graft dysfunction following transplantation. Although results from most of these trials have not been published, recent data suggest a beneficial effect of combined CXCR1/CXCR2 blockade following islet cell transplantation.⁹⁶ In another approach, antibody against CXCL8 (IL-8), a ligand for CXCR1 and CXCR2, has been evaluated as a topical therapy for psoriasis (ABCream) and is being marketed in China for that indication.

Based on mouse models, CCR2 and its ligands, particularly CCL2, have been suggested to play important roles in recruiting macrophages and thereby contributing to the pathogenesis of disorders such as multiple sclerosis, atherosclerosis, RA, systemic sclerosis, and lupus nephritis. Both small-molecule antagonists and antibodies to CCR2, as well as agents that block CCL2, have been undergoing clinical evaluation for treating some of these diseases. Although the beneficial effects of these drug candidates are not yet clear, many of the clinical investigations of CCR2/CCL2 blockade are in their early stages.⁹⁷ A recent trial using an anti-CCR2 antibody has shown efficacy in reducing serum C-reactive protein, which suggests a potential beneficial effect on inflammation related to risk for cardiovascular disease.⁹⁸

Effector/memory T cells can express at least 15 different types of chemokine receptors to produce complex, combinatorial patterns. Although the factors and mechanisms regulating chemokine receptor expression during T-cell activation and differentiation have not been studied extensively, it is clear that some receptors are induced as part of defined pathways for commitment to the T-cell lineage. Cells of the three principal effector/memory lineages of human CD4⁺ T cells, Th1, Th2, and Th17, are each wholly contained within the subsets expressing CXCR3, CCR4, or CCR6, respectively. Not surprisingly, then, the CXCR3, CCR4, and CCR6 genes are inducible, respectively, by the transcription factors T-bet, GATA-3, and ROR γ t, which are critical, respectively, for Th1, Th2, and Th17 differentiation. Given the expression of these receptors on subsets of effector/memory helper T cells implicated in a broad range of diseases, they might be considered good drug targets. Although antagonists have been developed for CXCR3 and CCR4, these inhibitors have undergone limited clinical testing for inflammatory disease, with as yet no encouraging results.^{99,100} However, one significant bright spot has been successful trials using an anti-CCR4 antibody to treat CCR4-expressing adult T-cell leukemia-lymphoma.¹⁰¹

The recent description of Th17 cells as a separate lineage has engendered tremendous interest because of the finding that these cells are important mediators of tissue injury in models of autoimmune disease.⁴⁹ Recognition of the relationship between Th17 differentiation and CCR6 have led to studies that demonstrated an essential pathogenic role for CCR6 in mouse models of arthritis, multiple sclerosis, and psoriasis. These data are likely to spur the development and testing of CCR6 antagonists for autoimmune disorders.

One of the most significant clinical outcomes from studies of the chemokine system is related to the use of CCR5 and CXCR4 by HIV-1 as coreceptors, together with CD4, for entry into cells.¹⁰² All clinical isolates of HIV-1 use CCR5 or CXCR4 (or both) as obligate coreceptors. CCR5 is the coreceptor of primary importance because viruses found in an individual early after infection use CCR5 (and not CXCR4), and individuals who are homozygous for an allele encoding a truncated and inactive CCR5 are highly resistant to HIV-1 infection. The latter observations, together with the apparent absence of deleterious consequences in CCR5-null individuals, has led to the development of CCR5 antagonists for use therapeutically to block viral entry in individuals infected with HIV-1. The first of these agents to reach clinical practice has been maraviroc, which has been shown to be effective in reducing viral loads in treatment-experienced individuals with CCR5-using HIV-1.¹⁰³ The availability of maraviroc will probably lead to its evaluation as an antiinflammatory drug; however, its utility for RA has not been demonstrated.¹⁰⁴

Despite the good general health of CCR5-null individuals, it has recently been reported that CCR5 deficiency is a strong risk factor for symptomatic disease in individuals infected with West Nile virus.¹⁰⁵ These data provide the first good evidence in humans supporting the presumption that CCR5 and other inflammation-associated chemokine receptors have roles in host defense, as well as a cautionary note on the use of chemokine receptor antagonists.

■ **TABLE 13.3**
Selected biologics currently in clinical use or clinical development

Name	Target	Type	Phase	Indications
Anakinra	IL-1	Human recombinant IL-1Ra	In clinic	Autoinflammatory syndromes, RA
IL-1 Trap/rilonacept	IL-1	Human IL-1R–Fc (IgG1) fusion protein	In clinic	Autoinflammatory syndromes, RA, gout, JIA
Canakinumab	IL-1β	Human MAb	In clinic	Autoinflammatory syndromes, RA
MABp1	IL-1α	Human Mab	1/2	Cancer, atherosclerosis, RA
Gevokizumab	IL-1β	Humanized MAb	2	RA, types 1 and 2 diabetes, Behçet disease, uveitis, acne, osteoarthritis
LY-2189102	IL-1β	Human MAb	1	Atherosclerosis, RA
Basiliximab	IL-2Rα	Chimeric (mouse/human) MAb	In clinic	Transplantation, uveitis, ulcerative colitis
Reslizumab	IL-5R	Humanized MAb (from rat)	2/3	Asthma, inflammation of skin and gastrointestinal tract
Tocilizumab	IL-6R	Humanized Mab	In clinic	RA, JIA, Castleman disease, ankylosing spondylitis
Clazakizumab	IL-6	Humanized MAb	2	RA, cancer, psoriatic arthritis
Sarilumab	IL-6R	Human MAb	3	RA, ankylosing spondylitis
Sirukumab	IL-6	Human MAb	2	Lupus erythematosus, lupus nephritis, RA
Ustekinumab	IL-12/23 p40	Human Mab	In clinic	Psoriasis, psoriatic arthritis, Crohn disease, sarcoidosis, palmoplantar pustulosis
Anrukinzumab	IL-13	Humanized MAb	2	Ulcerative colitis
Ixekizumab	IL-17	Humanized Mab	3	RA, psoriasis, psoriatic arthritis
Secukinumab	IL-17	Human MAb	3	Psoriasis, psoriatic arthritis, ankylosing spondylitis, RA, Crohn disease, multiple sclerosis, xerophthalmia
GSK-1070806	IL-18	Humanized MAb	1	Inflammatory bowel disease, diabetes mellitus
NNC-114-0005	IL-21	Human MAb	1	RA
SCH-900222	IL-23		2	Plaque psoriasis
Belimumab	BAFF/BlyS	Human MAb	In clinic	Lupus erythematosus
Sifalimumab	IFN-α	Human MAb	2	Lupus, dermatomyositis, polymyositis
Rontalizumab	IFN-α	Humanized MAb	2	Lupus
Denosumab	RANKL	Human MAb	In clinic	Osteoporosis, RA, hypercalcemia of malignancy, cancer
Fresolimumab	TFG-β 1, 2, and 3	Human MAb	2	Systemic sclerosis, renal sclerosis, pulmonary fibrosis, cancer, renal fibrosis, liver fibrosis
Etanercept	TNF-α	TNFR2-Fc (IgG1) fusion protein	In clinic	RA, JRA, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis
Infliximab	TNF-α	Chimeric MAb	In clinic	RA, psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, ulcerative colitis
Adalimumab	TNF-α	Human MAb	In clinic	RA, plaque psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, ulcerative colitis, JIA
Golimumab	TNF-α	Human MAb	In clinic	RA, ankylosing spondylitis, psoriatic arthritis
Pegsunercept	TNF-α	PEGylated TNFR2-Fc (IgG1) fusion protein	2	RA, JRA, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis
Certolizumab	TNF-α	PEGylated Fab' fragment of humanized MAb	3	RA, JRA, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis

BlyS, B-lymphocyte stimulator; IFN-α, interferon-α; IL-1, interleukin-1, IL-1Ra, IL-1 receptor antagonist; JIA, juvenile idiopathic arthritis; JRA, juvenile rheumatoid arthritis; RA, rheumatoid arthritis; RANKL, receptor activator of nuclear factor-κB; TGF-β, transforming growth factor-β.

GPCR S1P₁. Sphingosine-1-phosphate and S1P₁ mediate egress of lymphocytes from the thymus and lymph nodes.¹⁰⁹ This is of particular interest given the discovery that an immunosuppressive drug, fingolimod (FTY720), acts as a functional antagonist of S1P₁ *in vivo*.¹⁰⁹ Fingolimod has shown promise in the treatment of relapsing multiple sclerosis.¹¹⁰ Although the beneficial effects may be related to fingolimod's activity in blocking the egress of activated cells from lymph nodes, the drug has also been reported to increase numbers of suppressive Treg cells¹¹¹ and to inhibit Th17 cell differentiation¹¹² in mouse models.

OTHER CYTOKINES

IL-32 is another structurally distinct cytokine. Induced by IL-12 and IL-18, IL-32 activates NF-κB and p38 and enhances production of the other inflammatory cytokines. It is found in rheumatoid synovium. The function of IL-16 and IL-14 are uncertain.

Table 13.3 lists selected biologic agents currently in clinical use or clinical development.

Signal transduction in immune cells

■ ERIC P. HANSON ■ DANIELLA MUALLEM SCHWARTZ ■ MICHAEL BONELLI
 ■ JOHN J. O'SHEA ■ MARTIN ARINGER

- Response to environmental changes requires a variety of signaling pathways within the cell.
- The majority of these pathways start at cell surface receptors.
- Signals are commonly passed on via phosphorylation (kinases) or dephosphorylation (phosphatases).
- Several enzymes can be successfully targeted, and drugs blocking enzymes close to the surface are candidates for therapies for rheumatic diseases.

INTRODUCTION

Immune cells constantly survey their milieu and respond to intrinsic and extrinsic stimuli. This surveillance and response occur by a chain reaction of enzyme-mediated signaling events that are initiated when ligands bind specific receptors. The chemical modifications that take place are varied but often consist of the addition or removal of phosphate groups, small proteins (ubiquitin or sumo), or the generation of second messengers (cyclic adenosine monophosphate [cAMP], phospholipids). These intracellular signaling messengers eventually trigger key events such as activation of transcription factors, cytoskeletal changes, or release of preformed granules. This impacts cell shape and motility, metabolism, gene transcription, differentiation, proliferation, and cell death.

Conceptually, understanding signal transduction starts with considering the nature of the ligands and their receptors. Gases, for instance, directly traverse the plasma membrane, exerting their effects in the cytosol and nucleus. Cell-permeant ligands also traverse lipid bilayers and can bind cytosolic or nuclear receptors that function as transcription factors. Many other ligands, however, require interaction with some kind of membrane receptor, because they cannot cross the plasma membrane. For rheumatologists, most relevant ligands fall into this last category; for example, antigens and immune complexes, cytokines, chemokines, and bacterial, viral, and fungal components. To exert their effects, these ligands interact with a cell surface receptor that has a cytosolic component and initiate signal transduction cascades via modification of the cytosolic portion of the receptor.

Some cell-surface receptors have intrinsic catalytic activity, but others that lack enzymatic activity of their own associate with enzymes instead. Adapter molecules bring signaling molecules together, which act in concert to produce diverse responses. In some cases, the response to the engagement of receptors almost immediately changes cell shape or motility. Other receptors can induce cell death programs or the release of preformed mediators, which act in an autocrine or paracrine manner. In still other cases, ligand binding has delayed effects, altering gene expression and inducing cell growth and differentiation. In the latter cases, activation of DNA-binding transcription factors is often critical. All of these events contribute immune responses, and a few examples of each are provided here.

MEMBRANE-PERMEABLE LIGANDS THAT BIND INTRACELLULAR RECEPTORS

Factors that readily cross the plasma membrane represent the simplest conceptual means of modulating cell function. One of the simplest ligands is nitric oxide (NO), a key signaling molecule that regulates vascular tone.

Activated macrophages produce NO through an enzyme called *inducible nitric oxide synthase* (iNOS), a deficiency of which leads to defective cytokine signaling and impaired innate immune cell activation.¹ NO diffuses across cell membranes and activates soluble guanylate cyclase (sGC),² which converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). As a soluble second messenger within the cell, cGMP regulates protein kinases, ion channels, and phosphodiesterases, the latter of which serve to inactivate sGC in a negative feedback loop. Phosphodiesterases PDE5, a phosphodiesterase, interrupts this inhibitory feedback loop by converting cGMP back to GTP. Phosphodiesterase inhibitors, therefore, can be used to raise levels of cGMP, which act on cGMP-dependent protein kinase, leading to smooth muscle relaxation and vasodilatation. This provides the rationale for the use of PDE inhibitors in the treatment of pulmonary hypertension. Alternatively, drugs like riociguat activate sGC, and this agent is currently in phase 3 trials for the treatment of persistent or recurrent pulmonary hypertension.

Steroid hormone receptors with ligand-binding, DNA-binding, and transactivation domains

Almost as simple as gases are lipid-soluble ligands which bind to receptors that reside in the cytosol or nucleus. Arguably, for rheumatologists, the most important group of ligands in this category is the class of glucocorticoid hormones that bind nuclear hormone receptors. In addition, the nuclear hormone receptor superfamily includes the peroxisome proliferator-activated receptor (PPAR) and the receptors for vitamin A, vitamin D, estrogen, and thyroid hormone. Retinoid-related orphan receptor γ (ROR γ) is important for differentiation of type 17 helper T cells, but its natural ligands are poorly understood; nonetheless, ROR γ antagonists are being developed for use in autoimmune disease.³ Vitamin A, which binds to other retinoid receptors, inhibits interleukin-17 (IL-17) and upregulates Foxp3, thereby promoting the function of regulatory T cells.⁴ Similarly, the immunomodulatory effects of vitamin D are increasingly recognized, and drugs that target this family of receptors could emerge as important immunomodulatory agents. PPARs display isoform-specific effects on metabolism, cell differentiation and proliferation, and immune responses. These intracellular receptors have ligand-binding, DNA-binding, and transactivation domains and are often associated with coactivators or corepressors. PPAR agonists are widely used in the treatment of hyperglycemia and hyperlipidemia.^{5,6}

The aryl hydrocarbon receptor (AHR) binds a diverse array of exogenous compounds, including endogenous products of tryptophan that are generated by ultraviolet light exposure. AHR can regulate IL-17, IL-22, and Foxp3 expression and thus provides a means by which environmental toxins and ultraviolet light can have immunoregulatory actions^{7,8} and sustain mucosal innate lymphoid cells.

RECEPTORS WITH INTRINSIC ENZYMATIC ACTIVITY

Because most ligands are water soluble and cannot cross the plasma membrane, they must interact with some kind of receptor on the cell surface. Conceptually, the simplest architecture encompasses receptors that themselves are enzymes. These receptors include those that have intrinsic phosphotransferase (kinase), phosphatase, and guanylate cyclase activity.

An intensively studied class of such receptors is the receptor tyrosine kinase (RTK) family. These receptors have a ligand-binding domain outside the cell with a short transmembrane domain followed by a kinase domain on the intracellular portion of the receptor. Examples include receptors

for insulin, epidermal growth factor, vascular endothelial growth factor, platelet-derived growth factor, colony-stimulating factor-1, and stem cell factor (c-KIT).

Ligand binding to RTKs activates their enzymatic activity, and the receptors themselves become phosphorylated at specific sites. These sites are then bound by proteins that specifically recognize phosphotyrosine residues surrounded by specific sequences of amino acids via modules termed *src-homology 2* (SH2) domains. Of the many molecules that have SH2 domains, some are kinases or phosphatases, but others are molecules that lack enzymatic activity and instead serve as adaptor molecules. These adaptor molecules work in concert with enzymes to create platforms for the transmission of signals. For instance, the SH2-containing adaptor Grb2 brings the guanine-nucleotide exchange factor Sos into proximity with membrane-bound Ras, which activates downstream kinases including Raf1 and mitogen-activated protein kinase (MAPK). Inhibitors of p38 MAPK have been studied for the treatment of rheumatoid arthritis but exhibit unacceptable toxicity. In addition, there are data indicating that p38 isoforms can be protective.⁹ RTKs also activate phosphatidylinositol 3'-kinase (PI3-K) and phospholipase C γ (PLC γ); the consequences of activation of these pathways are discussed later.

Transforming growth factor- β (TGF- β) is a critical antiinflammatory cytokine that also promotes fibrosis and has been implicated in the pathogenesis of systemic sclerosis. The architecture of its receptor is similar to that of the RTKs in that it also contains an extracellular ligand-binding domain, a single transmembrane domain, and an intracellular kinase domain. In this case, though, the enzyme has serine/threonine kinase activity.¹⁰ There are many types of bone morphogenetic proteins that also bind receptors of this class. For instance, mutations of activin receptor 1A that activate its kinase activity underlie the disorder fibrodysplasia ossificans progressiva. Critical substrates for the TGF- β /activin receptors are receptor-activated Smads (R-Smads). Upon phosphorylation these cytosolic DNA-binding proteins translocate to the nucleus and activate gene transcription. In addition, two inhibitory Smads (I-Smads) function to negatively regulate TGF- β signaling.

Rather than possessing kinase activity, some receptors have phosphatase activity; that is, they remove phosphate groups from proteins. A large group of receptors include the receptor protein tyrosine phosphatases, which in certain cases remove phosphates that serve an autoinhibitory role. Thus these phosphatases are "activating."¹¹ For instance, CD45, an abundant receptor on the surface of immune cells, is a protein tyrosine phosphatase required for normal signaling in T and B cells; mutations of CD45 result in severe combined immunodeficiency.¹²

RECEPTORS THAT ASSOCIATE WITH ENZYMES

Some receptors without intrinsic enzymatic activity do the next best thing—they associate with enzymes. A large receptor family that associates with a small family of dedicated kinases is discussed first.

Type I/II cytokine receptors

More than 60 cytokines, interleukins, colony-stimulating factors, and hormones bind type I/II cytokine receptors (see Chapter 13). These receptors have extracellular ligand-binding domains and a single transmembrane domain. Their intracellular domain lacks enzymatic activity but instead binds Janus kinases (Jaks)—Jak1, Jak2, Jak3, or Tyk2—which selectively bind different cytokine receptor subunits¹³ (Fig. 14.1).

Upon ligand binding, the Jaks activate each other and phosphorylate the receptor. This provides docking sites for signaling molecules that have SH2 domains, especially signal transducers and activators of transcription (STATs), DNA-binding proteins that are phosphorylated by Jaks. Activated STATs translocate into the nucleus and regulate gene expression. There are seven members of the STAT family that have distinct functions, and genetic variants in STAT genes are associated with immune-mediated disease. The criticality of the Jaks in transmitting cytokine signals is vividly illustrated by genetic evidence; JAK3 mutations cause severe combined immunodeficiency and TYK2 mutations cause a primary immunodeficiency associated with atopic disease. The importance of the Jaks is also evidenced by the clinical utility of Jak inhibitors (jakinibs).¹³ Tofacitinib blocks Jak1, Jak3, and to a lesser extent Jak2. It is approved by the U.S. Food and Drug Administration for the treatment of rheumatoid arthritis in patients with inadequate responses to methotrexate, and European Medicines Agency approval is expected shortly. Other jakinibs are in development and clinical testing and have been approved for other indications. Many adverse effects of

Fig. 14.1 Type I/II Cytokine Receptors. The majority of cytokines bind this class of receptors. Unlike receptor tyrosine kinases, this class of receptor has no enzymatic activity. Instead, the different receptor chains specifically associate with one of four Janus kinases, JAK1, JAK2, JAK3 or TYK2. Upon ligand binding JAKs are activated and phosphorylate the cytokine receptors. This allows binding of various signaling molecules, one important family being the signal transducer and activator of transcription (STAT) family, which comprise STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B, and STAT6. Activated STATs translocate to the nucleus, bind DNA and regulate gene expression. A new class of immunomodulatory drugs is the Jak inhibitor or jakinib family.

jakinibs, including infection, anemia, leukopenia, and elevation of lipid levels, are directly related to their mechanism of action. Erythropoietin and other colony-stimulating factors signal via Jak2, which helps explain the adverse effects of anemia and leukopenia in patients receiving jakinibs. The elevation of lipid levels is similar to that seen with the IL-6 receptor blocker tocilizumab, which is consistent with the ability of jakinibs to inhibit IL-6 signaling.

As with the RTKs, engagement of cytokine receptors also leads to receptor phosphorylation and recruitment of SH2-containing proteins and activation of the Ras, Raf, and downstream MAPKs, which ultimately lead to activation of AP-1 family transcription factors. Cytokines can also activate PI3-K and mTOR. The mammalian target of rapamycin (mTOR), as its name suggests, is inhibited by the macrolide rapamycin, now licensed for the treatment of graft rejection as the drug sirolimus. Sirolimus and other mTor inhibitors are being tested in autoimmune diseases. Sirolimus does not directly bind mTOR but acts indirectly by associating with FK506-binding protein 12.

Antigen receptors and Fc receptors: the multichain immune recognition receptor family

The antigen receptors for T cells and B cells and the Fc receptor are multimeric receptor complexes. They belong to a family of more than 80 receptors, including killer inhibitor receptors, killer-activating receptors, dectin-1, and costimulatory receptors (CD28, CTLA-4).¹⁴ These receptors do not have intrinsic enzymatic activity, but instead associate with Src family protein tyrosine kinases—a family of at least 10 members that phosphorylate receptor chains and associated proteins. In T cells, the CD4 or CD8 coreceptor binds the major histocompatibility class II or class I molecule, respectively, and associates with the Src kinase Lck.^{15,16} In B cells and myeloid cells, other Src family kinases function as the first-tier activators (Fig. 14.2).

Fig. 14.2 Like the T-cell antigen receptor, the B-cell antigen receptor (BCR) and Fc receptor (FcR) depicted are multichain receptor complexes. Upon engagement by ligands, these receptors are phosphorylated by Src family tyrosine kinases (Lyn and Fyn in the case of BCR and FcR signaling). The phosphorylated receptor is bound by another kinase, Syk. This leads to phosphorylation of adapter molecules, including LAT and SLP-76. This allows the recruitment of a third family of tyrosine kinases, which includes Itk and Btk. Phospholipase Cγ (PLCγ) is activated by these signals, which generates diacylglycerol (DAG) and inositol triphosphate (IP₃). DAG activates protein kinase C (PKC) and IP₃ induces release of intracellular calcium (Ca²⁺) from the endoplasmic reticulum. Release of intracellular Ca²⁺ also induces entry of extracellular Ca²⁺ through calcium channels (CRAC), Orai1, and Stim1. Entry of magnesium ions is also important. Elevated levels of intracellular calcium activate the phosphatase calcineurin, which causes the translocation of nuclear factor of activated T cells (NFAT) to the nucleus. Multichain immune recognition receptors (MIRRs) also activate the phosphatidylinositol 3′ kinase (PI3-K), nuclear factor-κB (NF-κB), and mitogen-activated protein kinase (MAPK) pathways. Sirolimus inhibits mTor (mammalian target of rapamycin), which is downstream of PI3-K, whereas cyclosporine and tacrolimus inhibit calcineurin. Mutations of *ZAP70*, *Orai1*, and *BTK* result in primary immunodeficiency.

The phosphorylated receptor subunits recruit two important kinases, spleen tyrosine kinase (Syk) and Zap70, via SH2 domains. Mutation of *ZAP70* causes severe combined immunodeficiency with characteristic loss of CD8 T cells. Syk is used by the B-cell receptor and Fc receptors (see Fig. 14.2). Fostamatinib inhibits Syk and other kinases and has efficacy in rheumatoid arthritis.^{17,18} Adverse effects of fostamatinib include diarrhea, hypertension, and neutropenia. The basis of hypertension may not be related to effects on Syk, but has been speculated to be an off-target effect due to inhibition of vascular endothelial growth factor receptor, an RTK expressed by endothelial cells.

Receptor-associated tyrosine kinases also phosphorylate adapter molecules termed LAT and SLP-76, which in turn lead to the activation of a number of key downstream pathways. LAT binds multiple GAB2 family members and associated molecules that recruit SOS, the guanine nucleotide exchange factor. When localized to the plasma membrane, SOS is brought in proximity to its substrate RAS, which then triggers the serine threonine kinase Raf1 and MEK. A major pathway activated via LAT and SLP-76 is initiated by activation of PLCγ. This enzyme generates two important products, the transmembrane lipid diacylglycerol (DAG), and inositol triphosphate (IP₃). Production of second-messenger lipids activates yet another family of kinases that contain plextrin-homology domains, structures shared by many signaling and cytoskeletal proteins. In B cells, the key member of this kinase family is Bruton tyrosine kinase (BTK), which is mutated in X-linked agammaglobulinemia. Ibrutinib is a BTK inhibitor that has shown promise in the treatment of B-cell malignancies¹⁹; such inhibitors may also be useful in the treatment of autoimmune diseases.²⁰

Through the generation of DAG, antigen receptor signaling leads to activation of the RAS-RAF/MAPK pathway. DAG also activates serine-threonine kinases of the protein kinase C (PKC) family, of which at least 11 different isozymes exist. In T cells and B cells, activation of PKCθ and PKCγ leads to the phosphorylation and activation of the CARMA1-Bcl10-Malt1 complex.²¹ Together with activated TRAF6 and TAK1, these factors recruit and activate a complex composed of IκB kinase-α (IKKα), IKKβ, and IKKγ (NEMO), which activates nuclear factor-κB (NF-κB), a transcription factor involved in immunity and inflammatory disease.^{22,23} The complex does so by phosphorylating inhibitory proteins (IκBs) that hold NF-κB family members in the cytoplasm. Phosphorylation degrades IκBs, releasing NF-κB members for nuclear translocation. NEMO and IκBα mutations that impair NF-κB activation lead to a spectrum of developmental defects and immunodeficiency.^{24,25}

By activating PLCγ, antigen receptors generate IP₃, which releases calcium from the endoplasmic reticulum. This, in turn, causes plasma membrane channels to allow calcium to enter from outside the cell. Mutations in the PLCγ2 isoform lead to defective antibody production, cold-induced urticaria due to spontaneous mast cell degranulation, and autoinflammation.^{26,27} Calcium release-activated calcium (CRAC) channels are regulated by the products of two genes, *Orai1* and *STIM1*, mutation of which cause primary immunodeficiency and autoimmunity.^{28,29} Elevation of intracellular calcium concentration activates the phosphatase calcineurin, which dephosphorylates the transcription factor nuclear factor of activated T cells (NFAT). Calcineurin inhibition is the mechanism by which cyclosporine A and tacrolimus exert their immunosuppressive effects.

The early events in cell signaling and elevation of intracellular calcium levels lead to actin polymerization, alteration in cell shape, and changes in cell motility. The Wiskott-Aldrich syndrome protein carries out diverse functions involving actin polymerization, and mutations cause immunodeficiency, thrombocytopenia, eczema, and autoimmunity.³⁰ In addition to the role of calcium, the importance of magnesium flux in T-cell activation has recently been recognized: mutations of the magnesium channel *MAGT1* result in CD4 lymphopenia and immunodeficiency.³¹

For T cells, antigen signaling alone is not sufficient to fully activate the cells. CD28 is a critical costimulatory molecule that is activated by its ligands, CD80 and CD86. Such binding induces phosphorylation of CD28 by Lck, leading to activation of PI3-K, protein kinase B, and PLCγ. The immunomodulatory drug abatacept works by blocking CD28-dependent costimulatory signals. Related to CD28 is the molecule CTLA-4, which inhibits T-cell activation. Blockade of the inhibitory signal of CTLA-4 with the drug ipilimumab is used to treat cancers.³² Another important inhibitory receptor is PD-1 (programmed death 1). It is induced in T cells from patients with chronic viral infections, and blockade of PD-1 is useful in the treatment of cancer.³³

PTPN22 is a nonreceptor phosphatase linked to increased risk of various autoimmune diseases, including rheumatoid arthritis, systemic lupus erythematosus, and type 1 diabetes. The risk allele encodes a single amino acid change in the proline-rich SH3-binding domain (R620W), a site that binds the kinase CSK. Details on how this leads to autoimmunity are still under investigation; the mutant allele seems to affect T-cell and B-cell antigen receptor signaling, possibly by regulating Src family kinases. Expression of the risk allele is associated with ineffective negative selection of autoreactive lymphocytes.^{11,34-36}

Tumor necrosis factor receptor superfamily

Tumor necrosis factor (TNF) and related cytokines bind to a family of almost 30 different trimeric receptors (TNFRs), many of which have significance for rheumatologists. Members of this family include TNFR1, FAS, CD40, TNFRSF13C (BAFFR), TNFRSF13B (TACI), osteoprotegerin, and RANK. In the era of biologics, the importance of this family does not have to be emphasized.³⁷ TNFRs do not have enzymatic activity; instead, TNFR family members associate with adapters termed *TNFR-associated factors* (TRAFs) (Fig. 14.3).

These adapters and some TNFRs have a domain called the *TRAF domain*, which allows for homotypic interactions. TNFR1 does not contain a TRAF domain, but, via interaction with TRADD through their mutual death domains, couples to TRAF2 and the serine kinase RIP. Activation of TNFR1 leads to activation of the kinases TAK1 and MEKK3, which activate a second level of kinases. This activates MAPKs and IKK, and subsequently AP-1 and NF-κB.

All TRAFs except TRAF1 also contain a RING domain, which enables them to induce ubiquitination of themselves and of signaling molecules such as TAK1, RIP1, and NEMO. Different forms of ubiquitin direct proteins

Fig. 14.3 Soluble or membrane-bound ligands cause oligomerization of these tumor necrosis factor receptors (TNFRs), which are associated with adaptor proteins such as TRAFs (TNFR-associated factors) or TRADD (TNFR-associated death domain protein). Association with different adaptors leads to the activation of cell death, developmental, or activating pathways. Various TNFR members signal through the linear ubiquitin assembly chain complex (LUBAC), which leads to linear polyubiquitination of NEMO and RIP1. Activation of TNFR1 leads to recruitment of the kinases TAK1 and MEKK3, which trigger a second level of kinases, mitogen-activated protein kinase (MAPKs) and inhibitor of nuclear factor- κ B kinase (IKKs); this induces the transcriptional activity of AP-1 and nuclear factor- κ B (NF- κ B), respectively. FADD also has a death effector domain (DED) that binds DEDs in cysteine proteases (caspases). Activation of complex II leads to either apoptotic cell death or necrosis. Mutations in *TNFR1*, *HOIP-1* (a LUBAC component), and *IKBK*, which codes for NEMO (or IKK γ), lead to primary immunodeficiency and autoinflammatory disease. cIAP1, cellular inhibitor of apoptosis protein-1.

to various compartments in the cell, such as to the receptor signaling complex following cell stimulation or to the proteasome for degradation. Just as protein ubiquitination is an important aspect of signaling by immune receptors, so is deubiquitination, a process carried out by enzymes known as *deubiquitinases*, which are discussed later.

Another class of adaptors associated with the TNFR family is the inhibitor of apoptosis proteins (cIAP-1, cIAP-2 and XIAP). The cIAPs are E3 ligases that ubiquitinate signaling molecules, including themselves, which leads to the activation of MAPK and NF- κ B. Mutations in the closely related XIAP cause a disorder that mimics Crohn disease, but with additional signs of immunodeficiency.³⁸

Some TNFR family members (TNFR1, FAS, DR3-6) can also recruit a specialized series of proteases to induce cell death.³⁹ Receptors that can induce this death pathway associate with an adaptor called *Fas-associated protein with death domain* (FADD) through a motif termed the *death domain*. FADD also has a death effector domain that binds death effector domains in cysteine proteases (caspases). Activation of the caspase cascade culminates in apoptotic cell death. Mutations of FAS, FASL, and caspase-10 cause autoimmune lymphoproliferative syndrome, which results in the accumulation of B and T cells in lymph nodes due to failure of apoptosis. In addition,

somatic mutations in these proteins have been identified that lead to autoimmune disease.⁴⁰ Release of cytochrome C from mitochondria in response to different forms of cell stress can trigger caspase activation and the intrinsic cell death pathway through the formation of a macromolecular structure called the *apoptosome*.⁴¹

INNATE RECOGNITION OF PATHOGENS

The principal receptors that recognize products of microbial pathogens (pattern recognition receptors) are Toll-like receptors (TLRs), the nucleotide-binding oligomerization domain (NOD)-like family of receptors (NLRs), the RIG-I-like family receptors (RLRs), and C-type lectin receptors (CLRs).⁴²

TLRs are located either on the plasma membrane or intracellular organelles and recognize lipopolysaccharide (TLR4), peptidoglycans and glycolipids (TLR1, TLR2, TLR6), flagellin (TLR5), single-stranded RNA and bacterial DNA (TLR7, TLR9), and double-stranded RNA (TLR3).⁴³ Sensing of these molecular structures occurs via the leucine-rich repeat motif, which is found in a wide variety of signaling molecules including other classes of pattern recognition receptors. Closely related to TLRs is the IL-1 family of receptors, which share a conserved motif known as the *TIR* (Toll/IL-1 receptor) domain. TLRs have no enzymatic activity, but bind adapters including Myd88, TRIF, and Mal, which link the receptors to IL-1 receptor-associated kinases IRAK-1, IRAK-2, and IRAK-4.⁴⁴ By a series of phosphorylation and ubiquitination events similar to those occurring in TNFR signaling, NF- κ B, ERK, JNK, and p38 MAPK are activated. TLR3 and TLR4 can also induce type I interferons via activation of the TBK1 kinase through the activity of TRAF3, which has other important roles in the regulation of signaling.^{45,46}

In humans, the NLR family is composed of 22 members that respond to diverse products, including bacterial and viral products. Other stimuli are damage-associated molecular patterns such as K efflux, adenosine triphosphate, crystals of monosodium urate, cholesterol, and asbestos.⁴⁷ Gain-of-function mutations of NOD2 underlie the granulomatous inflammatory disease Blau syndrome, whereas polymorphisms of this gene are associated with Crohn disease.^{48,49} These receptors contain protein-protein interaction domains such as the caspase recruitment (CARD), pyrin (PYD), NOD,⁵⁰ and leucine-rich repeat domains. NLRs activate the adaptor protein RIP2 (also known as *RICK*), which leads to activation of NF- κ B and the MAPKs. Activation of other NLRs leads to formation of a large heptameric structure called the *inflammasome* (Fig. 14.4).

NLRs that contain a PYD domain interact with ASC (adaptor protein apoptosis speck protein with caspase recruitment), which then links to procaspase-1 through mutual CARD domain interactions. Active caspase-1 converts pro-IL-1 β and pro-IL-18 into their active forms. Mutations in NLRP3 lead to a spectrum of diseases called the *cryopyrin-associated periodic fever syndromes*. Use of anakinra and related IL-1 β -targeting therapies has been extremely useful in controlling symptoms in a majority of patients.⁵¹ Mutations in another pyrin family gene, *MEFV*, underlie the prototypical autoinflammatory disease familial Mediterranean fever.

Intracellular viral RNA is sensed by RLRs, which have CARD domains, central RNA-binding domains, and a C-terminal autoregulatory repressor domain.⁵² Viral RNA induces activation of RLRs and association with the adaptor protein MAVS/IPS-1. Via recruitment of the kinases IKK and TBK1, RLRs activate the transcription factors NF- κ B and IRF3⁵³ and trigger type I interferon production. The proinflammatory response following RLR signaling also involves activation of the caspase-1-dependent inflammasome pathways (described later).^{53,54}

CLRs recognize polysaccharide products of *Mycobacterium tuberculosis*, viruses, and fungi.⁵⁵ Members include Dectin-1, Dectin-2, the dendritic cell-specific ICAM3-grabbing nonintegrin (DC-SIGN), the macrophage mannose receptor, and the circulating mannose-binding lectin (MBL).⁵⁶ Following ligand binding, dendritic cell-bound CLRs induce phagocytosis and antigen presentation. Signaling is triggered either through association with adaptor molecules containing immunoreceptor tyrosine-based activation motif, such as Fc receptor γ chain (FcR γ), or associated kinases (Src, Syk, or Raf1) and phosphatases. Syk induces formation of the CARD9-Bcl10-Malt1 complex, which activates ROS, NF- κ B, and the NLRP3 inflammasome. Mutations of Dectin-1 or MBL cause primary immunodeficiency.⁵⁷

G PROTEIN-COUPLED RECEPTORS

The G protein-coupled receptors (GPCRs) constitute the largest class of receptors in the genome and comprise roughly 350 members divided

Fig. 14.4 Upon stimulation, nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) that contain a pyrin domain (PYD) elicit formation of the inflammasome, a large multimolecular complex that serves to process the proinflammatory caspase-1 to its mature form. Triggers of the inflammasome such as extracellular adenosine triphosphate (ATP), released at sites of cellular injury or necrosis, stimulate rapid K^+ efflux from the purinergic P2X7 receptor, triggering recruitment and pore formation by Pannexin-1. Other known triggers are phagocytosed crystals of monosodium urate, cholesterol, and microbial products. Activation of the NLRP leads to homotypic PYD interactions between the NLRP and a bridging protein, ASC. ASC associates with procaspase-1 via mutual CARD domains; this leads to a conformational change and converts procaspase-1 to active caspase-1, which processes immature forms of interleukin-1 β (IL-1 β) and IL-18, leading to their release. Mutations in *NALP3* are associated with susceptibility to the cryopyrin-associated periodic syndromes, which are effectively treated by blockade of IL-1 β . CPPD, calcium pyrophosphate dihydrate; MSU, monosodium urate.

into 19 groups. GPCRs include receptors that sense a variety of signals: light, odor, or taste; neurotransmitters (serotonin, dopamine, glutamate, epinephrine, norepinephrine, and acetylcholine); hormones; lipids (sphingolipids, leukotrienes, prostanoids); and chemokines and related factors.

GPCRs are seven-transmembrane-domain receptors and bind guanine nucleotide-binding proteins, complexes comprising α , β , and γ subunits. Upon activation, the α subunit exchanges guanosine diphosphate for guanosine triphosphate and dissociates from the β and γ subunits, which remain as heterodimers.⁵⁸ Some $G\alpha$ family members produce cAMP through the activation of adenylate cyclase, a 12-transmembrane-domain protein. In turn, cAMP activates protein kinase A (or cAMP-dependent protein kinase), which regulates a variety of enzymes. Recently, a link was made between cAMP generation and the NLRP3 inflammasome.⁵⁹ cAMP binds to NLRP3 directly to inhibit inflammasome assembly, and *in vitro*, downregulation of cAMP using phosphodiesterase inhibitors relieves this inhibition.

Some GPCR subunits activate PLC γ , which cleaves the membrane lipid phosphatidylinositol 4,5-bisphosphate into DAG and IP $_3$. DAG activates PKC and the Ras-Raf-MAPK pathway. In addition to inducing calcium mobilization and lipid phosphorylation, G $\beta\gamma$ dimers activate Rho family G proteins, which regulate actin filament assembly.⁶⁰ Actin filaments play a key role in the trafficking of immune cells and are crucial components of the cytoskeleton. Changes within the cytoskeleton, such as those induced by chemokine receptors, C5a anaphylotoxin, FMLP receptor, or histamine, are critical and are among the most rapid events induced by cell-surface receptors. The receptor for sphingosine-1-phosphate, a signaling lipid molecule present in blood and lymph, is highly expressed on endothelial cells and is important for the egress of lymphocytes from the thymus and lymph nodes.⁶¹ Fingolimod, a drug approved for multiple sclerosis, downmodulates this receptor and thereby interferes with lymphocyte trafficking.⁶²

SUMMARY

The molecular biology revolution and completion of the human genome permitted the development of the biologic therapies, which have revolutionized the practice of rheumatology. These same advances have allowed the discovery of key immunologic receptors and their signaling pathways. The first oral small-molecule inhibitors targeting key nodes in signal transduction such as the jakinibs, Syk inhibitors, and other agents have entered the rheumatologist's armamentarium. These drugs already have considerable impact on the practice of rheumatology. In addition, the discovery of these pathways has provided insight into the immunopathogenesis of autoimmune, autoinflammatory, and immunodeficiency disorders. As we learn more and more about signaling in immune cells, new therapeutic opportunities will emerge along with opportunities for assessment of disease risk, diagnosis, and better disease monitoring. Ideally, these insights will ultimately facilitate long-term remissions and possibly the cure of rheumatic diseases.

Principles of adaptive immunity

■ SERGEI P. ATAMAS

- Cells of the adaptive immune system, T and B lymphocytes, produce large repertoires of T-cell receptors and immunoglobulins using somatic gene recombination.
- In contrast to the innate immune system, the adaptive repertoire of lymphocytes can recognize and eliminate a broad variety of new antigens not previously encountered by the host or the host's species. Clonal selection preserves and expands those lymphocytes whose products prove useful in protecting the host.
- The adaptive immune system has an inherent potential for self-reactivity, or autoimmunity. The potential to induce autoimmunity is usually controlled by a combination of deletional and regulatory mechanisms jointly referred to as *immune self-tolerance*.
- Immune receptor triggering involves the movement of receptors and costimulatory molecules into specialized complexes followed by the assembly of enzymatic cascades within the cells' interior.
- Helper T cells of diverse phenotypes control the functioning of the adaptive immune system.
- All these processes provide targets for therapeutic manipulation in autoimmune diseases.

INTRODUCTION

Most rheumatic diseases are autoimmune in nature or have an autoimmune component. Although the innate immune mechanisms often deliver the immediate damage in rheumatic diseases, the primary defect leading to autoimmunity—failure to maintain tolerance to the body's own tissues—affects the adaptive immune system. The purpose of the immune system is to provide protection against microscopic invaders and their toxic products. As a result of coevolution with pathogens, species acquired innate ability to recognize the pathogen-associated molecular patterns and to fight off the microscopic intruders. Such innate immunity is not strict in specifically identifying the foreign molecules: anything that resembles commonly occurring infections is considered as a sign of a potential problem. Therefore general molecular patterns rather than specific molecules are recognized through the innate pattern recognition receptors (PRRs) (see Chapter 16). Although the innate immune system is very effective at its job, its limitation is that the spectrum of PRRs is shaped solely by the history of host-pathogen interactions. As a result, innate immunity fails in situations in which a new infectious agent appears that has not been previously encountered in the history of the host species. By constantly mutating, pathogens (viruses, bacteria, fungi, and protozoa) generate new molecular patterns that may avoid recognition by the preexisting PRRs. There is a need for a kind of immunity that is able to adapt to whatever unforeseen pathogens attack the host. The adaptive (to the novelty of the future) immune system developed later evolutionarily than the innate immune system, yet they are tightly integrated into a very sophisticated cellular and molecular protective system. The cells of adaptive and innate immunity use a complex spectrum of cell-surface molecules and soluble factors to orchestrate a precisely timed and highly effective protection at the microscopic level.

Both innate and adaptive parts of the immune system must first recognize their targets; this process is commonly referred to as the *cognitive phase*. It is followed by the *effector phase*, during which the immune cells respond to the threat. The cognitive phase defines the central difference between innate

and adaptive immunity. In the innate immune system, the PRRs are rather ubiquitously expressed and are ready to bind pathogen-associated molecular patterns immediately, which leads to instant activation of the effector phase. In contrast, the adaptive recognition system is constructed to identify and respond effectively to myriads of unpredictable new foreign molecules (antigens) without confusing them with the body's own molecules. This process is more complex and less efficient than the functioning of innate immunity, and therefore it is slower. To save time during the subsequent encounters with the newly “learned” antigens, adaptive immunity is capable of retaining specific memory of previous experiences and responds much faster and more effectively the next time a previously encountered antigen threatens the host.

THE ADAPTIVE IMMUNE SYSTEM

Numerous subpopulations of B and T lymphocytes, or B and T cells, compose the adaptive immune system. When precursors (progenitors) of immune cells differentiate and mature into numerous subsets of functional cell types, they differentially express various functional molecules—“clusters of differentiation” (CDs)—on their cell surface. These molecules are often used as markers of immune cell subtypes. For example, CD19 and CD20 are expressed on B cells, whereas CD3 and CD28 are expressed on T cells. Despite phenotypic diversity and functional specialization of lymphocytes, each of them is ultimately defined by its antigen receptor, whereas adaptive immunity as a whole is defined by the vast repertoires of lymphocytes bearing their unique receptors for antigens.

The B cells terminally differentiate into plasma cells, which are the sole source of specialized protective molecules synonymically called *immunoglobulins*, or *antibodies*, or *γ-globulins*. The secreted antibodies mediate the so-called humoral (or fluid-based) immunity. Their goal is to circulate through the body in fluids, or humors, and bind to and neutralize extracellular microbes or any other targets that can be present outside cells. However, some pathogens can evade humoral immunity by hiding in the host's cells as intracellular parasites and thus becoming inaccessible to antibodies. In such cases, cytotoxic T cells will recognize and kill the infected host cells, and thus prevent further spreading of the infection. The innate immune cells (e.g., macrophages that phagocytize and digest microbes) and adaptive immune cells work together to provide molecular protection to the body. Even at this superficial level of analysis, there appears to be a need to integrate and orchestrate the activities of various cell populations in the humoral and cell-mediated branches of immunity. A major population of T cells acts as such a central regulator of immunity. They are CD4+ helper T cells, the principal regulator of the entire immune response, which produce cytokines regulating activities of other types of immune cells.

Clonal selection and expansion of lymphocytes

The adaptive immune system can respond to previously unencountered antigens. A preprogrammed system such as the innate immune system, by definition, cannot be instructed in dealing with the unknown. The adaptive immune system uses the only successful strategy in the face of the unknown—diversification with subsequent selection of useful elements. The more broadly a system is diversified, the more likely the possibility that at least one of the diverse elements will, by random chance, be adaptive in a new, changed environment. Such an adaptive element, no matter how small initially, can be expanded to ensure adaptation of the whole system to the new environment.

Each individual lymphocyte is functionally defined by its antigen-specific receptor, either B-cell receptor (BCR) or T-cell receptor (TCR). On its cell

Fig. 15.1 A model of immunoglobulin G (IgG) is shown on the left, a model of surface IgM B-cell receptor is shown in the middle, and a model of T-cell receptor $\alpha\beta$ is shown on the right. Constant (C) and variable (V) domains are indicated, as well as heavy (H) and light (L) chains of immunoglobulins.

Fig. 15.2 This diagrammatic representation shows features common to B-cell receptor and T-cell receptor genes. Gene recombination randomly joins one of each variable (V), diversity (D), and joining (J) gene segments together to form a variable domain-encoding V-D-J region. Following transcription of this region, as well as the constant (C) gene segments, into pre-messenger RNA, the final messenger RNA transcript is formed by RNA splicing.

surface, each lymphocyte expresses multiple (tens to hundreds of thousands) copies (molecules) of antigen-binding receptor of only one specificity. Slight variations in the structure of antigen receptors among individual lymphocytes lead to a tremendous variability of antigen-binding specificities. It has been estimated that about 10^{11} diverse BCRs can be generated in the bone marrow and 10^{18} diverse TCRs can be produced in the thymus, with about 10^7 BCR and 10^7 TCR specificities present in a human at any given time. Each of the receptors is stochastically generated and has a binding specificity for a random, unpredictable antigen. As a result of the presence of such a broad repertoire of lymphocytes, chances are that no matter what new antigen is encountered by the organism, at least one (or likely more than one) lymphocyte will happen to be responsive to that antigen. In a simplified scenario, binding of an antigen molecule to an antigen receptor stimulates proliferation of the lymphocyte that expresses the receptor. When a lymphocyte proliferates, its offspring inherit the antigen-receptor specificity and thus form an expanding clone (i.e., multiple copies of a lymphocyte with exactly the same specificity). The proliferating lymphocytes also undergo functional activation and eliminate the antigen in the effector phase of the immune response. Thus antigens select their own killers—lymphocytes that are the “fittest” for dealing with these specific antigens—from a vast variety of the preexisting randomly generated repertoire of lymphocytes. Such clonal selection of lymphocyte repertoires by antigens—a kind of cellular Darwinism—is the basis of functioning of the adaptive immune system.

Antigen receptors of lymphocytes

Immunoglobulins can be either membrane bound (acting as the BCRs) or soluble effector molecules (Fig. 15.1). The Y-shaped immunoglobulin molecule consists of four chains: two identical heavy chains and two identical light chains (see Fig. 15.1). There are nine heavy-chain isotypes (α 1, α 2, δ , ϵ , γ 1 to γ 4, and μ) that determine immunoglobulin class and subclass (IgA1, IgA2, IgD, IgE, IgG1 to IgG4, and IgM, respectively) as well as the effector mechanisms that a particular antibody can elicit. Two light-chain isotypes (κ and λ) can associate with any heavy chain. The light chains are folded into a variable and a constant domain, whereas the heavy chains are folded into a variable domain in addition to three (α , γ , and δ) or four (ϵ and μ) constant domains. Mature naive B cells express IgM and IgD with identical variable domains. These cell-surface immunoglobulins are coexpressed with Ig α and Ig β chains, forming together a functional BCR capable of antigen recognition and binding (see Fig. 15.1), which leads to initiation of intracellular signaling and subsequent clonal selection of the antigen-specific B cells.

The TCR is a cell-surface heterodimer composed of α and β chains or, in about 5% of T cells, of γ and δ chains. Each of these chains is folded into two domains, one of which is the variable domain that determines antigen specificity, and the other of which is the constant domain that includes hydrophobic sequences that anchor the receptor to the surface of the T cell (see Fig. 15.1). The TCR associates with four other invariant chains at the cell surface: the CD3 proteins γ , δ , ϵ , and ζ chain. Collectively they are known as the TCR complex. Unlike immunoglobulins, the TCRs cannot bind antigens directly. Instead, the TCR-chain variable domains bind antigen-major histocompatibility complex complexes, as discussed later.

A functionally important structural similarity between BCRs and TCRs is that they have variable domains that function to bind antigens. Within these variable domains are hypervariable regions, also called *complementarity-determining regions*, that define the complementarity of the antigen receptors to antigens in terms of geometric shape and spatial distribution of electric charges and/or hydrophobic patches. Variations of amino acid sequences in these hypervariable regions are the basis for the spectrum of antigen-binding specificities within an adaptive immune repertoire.

Generation of diversity of antigen receptors

A newly generated B cell expresses BCRs and a newly generated T cell expresses TCRs of a unique, randomly generated specificity. These immune repertoires develop in a unique process of somatic chromosomal recombination of gene segments in the antigen receptor loci of DNA. This permanent change to DNA, more specifically referred to as *V(D)J recombination*, occurs only in lymphocytes.¹ The variable regions of antibodies and TCR chains are encoded in DNA by multiple different variable (V), diversity (D), and joining (J) gene segments. During somatic recombination of DNA, select V, D, and J segments are brought together (Fig. 15.2). Depending on the gene (Ig heavy chain, Ig light chain, TCR α , TCR β , TCR γ , TCR δ), the number of V segments can vary from dozens to hundreds, the number of D segments from none to a few, and the number of J segments from a few to dozens. The random V(D)J recombination leads to combinatorial diversity of antigen receptors. This process is subject to complex regulation by numerous factors, including TdT, RAG1, RAG2, Ku70, Ku80, XRCC4, DNA ligase 4, DNA-PKcs, Artemis, and other factors that continue to be vigorously investigated. In addition to the variability produced by combinatorial diversity, even more variability is added by junctional diversity resulting

from imprecise joining of the V, D, and J segments; that is, insertions and deletions that occur during V(D)J gene segment recombination. These mechanisms are operative during lymphocyte maturation. In addition, mature naive B cells, but not T cells, undergo receptor editing, somatic hypermutagenesis, and isotype switching processes that are discussed briefly in the section devoted to B cells.

B CELLS AND HUMORAL IMMUNITY

B-cell development

Maturation of B cells in the bone marrow (Fig. 15.3) occurs under the control of cell-surface molecules and soluble growth factors produced by bone marrow stromal cells,^{2,3} as well as several key transcription factors.^{4,5} Pro-B cells begin rearrangement of the Ig heavy-chain (H) genes and express the pro-BCR. DJ rearrangements begin first, and V to DJ rearrangements follow. Productively rearranged μ chains are expressed on the cell surface with a surrogate light chain and Ig α and Ig β . This pre-BCR induces cell division and the generation of nondividing small pre-B cells. It also suppresses further Ig heavy-chain (H) gene recombination (allelic exclusion) by decreasing RAG expression and appears to make further VH genes less accessible to the recombination machinery. The subsequent rearrangement of the light chain leads to expression of the mature BCR, in which the surrogate light chain in the pre-BCR is replaced by a mature κ or λ chain. Expression of the BCR leads to suppression of further light-chain recombination; however, allelic exclusion at the light chain locus is “leaky,” and about 10% of B cells express two separate light chains. At this stage the lymphocyte becomes an immature B cell expressing surface IgM (BCR), and it is at this stage that induction of immune tolerance occurs. Because the mechanism of generating BCR specificity is intrinsically stochastic, the likelihood is high that many (up to 60%) of the newly generated BCRs will, by a random chance, be reactive against own-body molecules. If the BCR on an immature B cell reacts with own-body molecules (self-antigens), then it should be removed to avoid the development of a self-reactive, autoimmune clone of B cells. Such clonal deletion occurs by apoptosis, but not instantly. First, autoreactive immature B cells become anergic (not able to proliferate in response to stimulation). Then, a unique process called *receptor editing* occurs, in which immunoglobulin rearrangements continue even after assembly of a functional BCR.^{6,7} This mechanism, in contrast to anergy or deletion, spares many autoreactive B cells by replacing their receptor with a new one, possibly one that is not

self-reactive. However, if the new receptor is also self-reactive, such self-reactive B cell becomes apoptotically deleted. Censoring of potentially autoreactive B cells may also take place before the BCR is fully matured, at the level of pre-BCR,⁸ or in the mature naive B cell, to maintain peripheral tolerance.⁹ The process of receptor editing may be either inhibited or accelerated in patients with rheumatic autoimmune diseases. Such impairments contribute to the pathogenesis of autoimmune disorders by promoting the uncontrolled emergence and/or persistence of autoreactive B-cell clones.^{10,11}

Immature B cells that emigrate from the bone marrow are known as *transitional B cells*. The transitional cell pool is homeostatically controlled to maintain mature B-cell numbers. Mature naive B cells express membrane-bound monomeric IgM (as opposed to soluble IgM pentamer) and IgD with identical variable domains. This is accomplished by alternative RNA splicing. These IgM and IgD-coexpressing B cells will survive between 3 and 8 weeks if they successfully enter primary follicles in secondary lymphoid tissues. This is where they will encounter specific antigen. If that happens, the B cell will interact with helper T cells and become activated. Some B cells will proliferate and differentiate directly into immunoglobulin-secreting plasma cells, whereas others will enter into nearby primary follicles. These primary follicles become secondary follicles with germinal centers where large proliferating B cells (centroblasts) undergo somatic hypermutation and class switching before becoming nonproliferating centrocytes. Affinity maturation, in which affinity of antibodies to antigens increases over time, is a phenomenon unique to B cells. The mechanism by which this is achieved is somatic hypermutation, in which additional sequence variation is introduced into the recombined V(D)J sequence. Some activated B cells that have survived the affinity maturation process will home to other secondary lymphoid tissues or bone marrow and differentiate into plasma cells secreting IgG, IgA, or IgE high-affinity antibodies; others will become quiescent, long-lived memory B cells. The immunoglobulin class switching, or isotype switching, upon B-cell stimulation involves recombination of so-called switch regions of DNA that are located upstream of each constant heavy-chain gene segment. This process moves the rearranged VDJ segment closer to the intended constant heavy-chain gene segment by excising the intervening sequence.^{12,13} An enzyme activation-induced deaminase is critical for both somatic hypermutation and isotype switching.^{14,15}

The survival of peripheral B cells depends critically on B-cell activation factor of the tumor necrosis factor family (BAFF), also called BlyS, and a proliferation-inducing ligand (APRIL). Elevated levels of BAFF and APRIL have been associated with autoimmunity. Inhibitors of BAFF and/or APRIL are promising agents for treatment of rheumatic diseases.¹⁶

Fig. 15.3 Hematopoietic stem cells (HSCs) differentiate into non-self-renewing hematopoietic multipotential progenitors (MPPs), then into lymphoid-primed multipotential progenitors (LMPPs), and then into common lymphoid progenitors (CLPs). Expression of various markers is shown for each differentiation stage. Immature B cells, which are generated from fraction D cells, exit the bone marrow and reach the spleen, where they mature into peripheral mature B cells and plasma cells. Factors that regulate B-cell development at the indicated stages are shown at the bottom. CD20 is a target for therapeutic monoclonal antibodies (rituximab), which deplete B cells in patients with autoimmune disorders, including rheumatic diseases. This cell-surface molecule is expressed on B cells during the indicated stages of development, as well as on activated and memory B cells, but it is lost during terminal plasma cell differentiation. Ig, immunoglobulin; IL, interleukin. (Adapted by permission from Macmillan Publishers Ltd: Nagasawa T. Microenvironmental niches in the bone marrow required for B-cell development. *Nat Rev Immunol* 2006;6:107-16, copyright 2006.)

B-cell activation and functions

The BCR as well as soluble immunoglobulin can bind both linear and conformational (three-dimensional) epitopes on a wide variety of molecules, including protein, polysaccharide, and lipid antigens. They recognize such antigens directly, without the need for antigens to be presented to them. Certain antigens (thymus-independent antigen) can activate B cells without the need for helper T cells, but many require T-cell help and are thymus dependent.

Upon BCR ligation with antigen, numerous intracellular signaling molecules become activated, such as kinases of the Src family, Syk, and Btk; also, Ca^{2+} mobilization and Ras activation, as well as phosphorylation of $\text{Ig}\alpha$ and $\text{Ig}\beta$ chains, takes place. Activation of a downstream signaling cascade ensues (see Chapter 14), with final activation of a series of transcription factors, resulting in dramatic changes in the pattern of gene expression and in overall B-cell activation.^{17,18} Engagement of the BCR by an antigen is not sufficient by itself to activate a B cell. Instead, the BCR relies on costimulatory receptors to bring about B-cell activation.¹⁹ The costimulatory receptors CD19 and CD21 form a noncovalent complex that is co-ligated with the BCR to promote B-cell activation. Upon phosphorylation, CD19 recruits phosphatidylinositol 3'-kinase, Src family kinases, and Vav to facilitate activation of the mitogen-activated protein kinase pathways and Ca^{2+} mobilization. Negatively regulating coreceptors such as CD22, CD72, and $\text{Fc}\gamma\text{RIIB1}$ inhibit B-cell proliferation and Ca^{2+} mobilization. Thus the activation state of B cells is determined by the integration of stimulatory and inhibitory signaling events. This signaling system is very finely tuned, and disturbances in the signaling/cosignaling may lead to autoimmune activation of B cells that start producing antibodies against the body's own tissue, particularly in rheumatic diseases.

The principal function of B cells is to differentiate into plasma cells and secrete antibodies. When secreted as soluble molecules, antibodies perform various protective effector functions following their binding to pathogens, such as direct neutralization, activation of the complement system or of antibody-dependent cellular cytotoxicity, or opsonization of pathogens for phagocytosis. These are innate immune mechanisms that are discussed in detail in Chapter 16 of this book. In addition, B cells, along with dendritic cells and macrophages, can serve as antigen-presenting cells (APCs) for T lymphocytes (see later). In their capacity as APCs, B cells express cell-surface molecules B7.1 (CD80) and B7.2 (CD86) that bind to CD28 or cytotoxic T-lymphocyte antigen 4 (CTLA-4 or CD152) expressed on T lymphocytes and provide either activating (CD28) or inhibitory (CTLA-4) costimulatory signals (see section on **T-cell activation** later). Resting B cells express low levels of CD86. Their activation leads to expression of CD80 and enhanced expression of CD86. Dysregulated expression of these molecules on B cells has been associated with autoimmune and rheumatic diseases.

T CELLS AND CELL-MEDIATED IMMUNITY

Recognition of antigens by T cells

Unlike immunoglobulins, TCRs cannot bind antigens directly. Instead, antigens for TCRs have to be processed and presented to T cells by a specialized class of molecules called *human leukocyte antigen* (HLA) proteins that are encoded in the major histocompatibility complex (MHC) of genes (Fig. 15.4a). In other words, T cells recognize antigens presented in the context of MHC molecules. The terms *HLA* and *MHC* are often used interchangeably to denote the same genomic region and corresponding protein products in humans. There are two classes of these cell-surface heterodimeric glycoproteins: class I (e.g., HLA-A, HLA-B, and HLA-C) and class II (e.g., HLA-DP, HLA-DQ, and HLA-DR). The class I proteins consist of a three-domain α chain noncovalently complexed with β_2 -microglobulin. They are expressed on the surface of most nucleated cells and bind the CD8 molecule expressed on T cells. The class II molecules consist of an α and a β chain. Each of these two class II chains has a two-domain structure. Class II molecules are constitutively expressed on so-called professional APCs, such as dendritic cells, macrophages, and B cells, but can be induced on other cell types. They bind a T-cell coreceptor, CD4. All the HLA molecules therefore have a four-domain structure with a peptide-binding site formed between the two domains most distal from the cell surface ($\alpha 1$ and $\alpha 2$ for class I and $\alpha 1$ and $\beta 1$ for class II molecules). The peptide-binding groove, lying between two α helices and floored by a β -pleated sheet, shows degenerate binding specificity. Class I molecules bind peptides limited to about 8 to 10 amino acids in length because of the pockets that anchor the peptide at the ends of the binding site. Class II molecules, which are free of this constraint, bind peptides between 13 and 25 amino acids long.

In each individual, each class of MHC is represented by multiple different genes (HLA-A, HLA-B, and HLA-C; HLA-DP, HLA-DQ, and HLA-DR), and each gene is highly polymorphic (having dozens to hundreds of genetic variants in a population). MHC haplotypes (sets of genes inherited from each parent) are codominantly (equally) expressed. As a result of the polygenic and polymorphic nature of the MHC genes, each individual in an outbred population expresses a unique set of MHC proteins. This genetic diversity of the MHC loci defines each individual's unique spectrum of peptides that can be presented to the TCRs.

In contrast to presentation of peptides by MHC molecules, lipid and glycolipid antigens are presented by CD1 molecules. These transmembrane proteins expressed on APCs are homologous to MHC class I molecules and noncovalently paired with β_2 -microglobulin.^{20,21} Five CD1 molecules have been identified in humans (CD1a to CD1e). They present self or foreign lipid antigens such as microbial lipids derived from the cell walls of mycobacteria to $\alpha\beta$ and $\gamma\delta$ T cells (CD1a, CD1b, CD1c) or to natural killer T cells (CD1d).

Processing of antigens for presentation to T cells

The purpose of the MHC class I pathway is to survey for possible intracellular problems such as viral or bacterial infections or malignant transformation and report such problems to CD8+ T cells. In contrast, the purpose of the MHC class II pathway is to survey the overall extracellular environment and to present antigens in it to the central regulating and integrating immune cell type, CD4+ T cells. The mechanisms of these antigen processing pathways differ substantially (Fig. 15.4b and c).

In the class I pathway, a significant proportion of newly synthesized intracellular proteins is degraded by proteasomes, which are multisubunit protein complexes with a number of different proteolytic activities. It is likely that rapid synthesis of viral proteins in the host cells' ribosomes occurs with numerous errors, which leads to accumulation of defective ribosomal products. Such proteins are the major supplier of peptides for the class I pathway.²² Peptides generated by proteasomes are transported by TAP (transporter associated with antigen processing) across the membrane of the endoplasmic reticulum, whereas class I MHC molecules translated by ribosomes at the endoplasmic reticulum membrane are chaperoned by calnexin until they associate with β_2 -microglobulin. Additional chaperones, including calreticulin and tapasin, facilitate peptide loading. The completed MHC-peptide complex is transported through the endoplasmic reticulum and the Golgi apparatus to the cell surface.

Class II MHC molecules present antigens internalized by professional APCs. Protein antigens taken up by phagocytosis, macropinocytosis, endocytosis, and receptor-mediated endocytosis are delivered to an endosomal compartment that contains class II MHC molecules. Peptides are generated from these proteins by proteases that are active in this acidic environment. MHC class II heterodimers, stabilized by their association with the invariant chain (Ii), are targeted to this endocytic compartment through a signal in the cytoplasmic tail of the invariant chain. Once there, the Ii is sequentially digested, so that only a fragment (class II-associated Ii peptide [CLIP]) is left in the peptide-binding site. HLA-DM and HLA-DO (also encoded in the MHC class II region) then catalyze the exchange of CLIP for antigenic peptides, after which the antigen-loaded MHC class II molecules are transferred to the cell surface.

Recent studies emphasized the role of a process called *autophagy* in modulating MHC class I and class II presentation of cytoplasmic and nuclear antigens.^{23,24} Autophagy is only one of numerous mechanisms of a process called *cross-presentation*, in which MHC class I molecules present extracellular proteins to CD8+ T cells.^{25,26}

In the CD1 pathway, foreign lipid antigens are taken up through internalization of clathrin-dependent apolipoprotein E-lipid complexes bound to the low-density lipoprotein (LDL) receptor; phagocytosis of particulate material or whole pathogens; C-type lectins, which can bind mannose residues on glycolipids; and scavenger receptors, which can bind modified forms of LDL and apoptotic cells. Loading of self-lipids onto CD1 occurs through a poorly characterized mechanism that involves microsomal triglyceride transfer protein.^{20,21}

T-cell development

T-cell development occurs in the thymus (Fig. 15.5), controlled by complex regulatory mechanisms.^{27,28} The most immature thymic T cell, the early T-lineage progenitor, develops from a bone marrow-derived hematopoietic cell precursor. These progenitors lack the cell-surface proteins CD4 and CD8 (double-negative cells). They are also negative for the interleukin-2 receptor α chain, CD25, but positive for the adhesion molecule CD44. As

Fig. 15.4 Presentation of antigen peptides by major histocompatibility complex (MHC) molecules (a), as well as class I (b) and class II (c) antigen-processing pathways, are shown. In the class I pathway, proteins with errors are tagged with ubiquitin for degradation and degraded by proteasomes into peptides, which are delivered into endoplasmic reticulum, loaded into nascent MHC class I molecules, and transported via the Golgi complex to the cell surface. In the class II pathway, the internalized pathogens activate Toll-like receptors (TLRs), which leads to maturation of phagosomes, formation of phagolysosomes, loading of MHC class II molecules with peptide fragments of the bacteria or viruses that are formed by lysosomal proteases, and transport in endolysosomal tubules to the cell surface. Autophagosomes also fuse with lysosomes and serve as an additional source of peptides, including endogenous peptides, for MHC class II presentation. Ag, antigen; APC, antigen-presenting cell; β_2m , β_2 -microglobulin; mRNA, messenger RNA; TAP, transporter associated with antigen processing; TCR, T-cell receptor. (b and c, Adapted by permission from Macmillan Publishers Ltd: Vyas JM, Van der Veen AG, Ploegh HL, et al. The known unknowns of antigen processing and presentation. *Nat Rev Immunol* 2008;8:607-18, copyright 2008.)

the progenitors undergo differentiation, they acquire CD25, lose CD44, and complete somatic rearrangement of the gene loci encoding the TCR β , γ , and δ chains. If both TCR γ and δ chains undergo productive rearrangement, then the T cell expresses this heterodimer and becomes committed to the $\gamma\delta$ lineage. If, however, the β chain undergoes productive rearrangement first, then the TCR β chain is expressed on the cell surface along with an invariant chain called pre-T α , forming the pre-TCR complex. Expression of the pre-TCR stimulates proliferation of these T cells, suppresses VDJ recombination in the second TCR β locus on the allelic chromosome, and

stimulates recombination in the TCR α locus. Failure to successfully undergo any of these steps causes apoptotic death of the maturing T cell. After acquiring the CD4 and CD8 coreceptors (double-positive cells), the thymocytes undergo the selection process. Positive selection allows the small percentage of the thymocyte population capable of recognizing MHC-peptide complexes to mature further, leaving the remainder to die by apoptosis. Similar to newly emerging B cells in the bone marrow, many of the TCRs generated through the stochastic mechanisms in the emerging thymic T cells are autoreactive. Negative selection deletes T cells that bind

Fig. 15.5 Thymic lobes are organized into discrete cortical and medullary areas, each of which is characterized by the presence of particular stromal cell types as well as thymocyte precursors at defined maturational stages. Thymocyte differentiation can be followed phenotypically by the expression of cell-surface markers, including CD4, CD8, CD44, CD25, CD69, and CD62L, as well as the status of the T-cell receptor (TCR). Interactions between thymocytes and thymic stromal cells drive T-cell maturation, resulting in the generation of self-tolerant CD4+ helper and CD8+ cytotoxic T cells, which emigrate from the thymus to establish the peripheral T-cell pool. MHC, major histocompatibility complex. (Adapted by permission from Macmillan Publishers Ltd: Anderson G, Jenkinson EJ. Lymphostromal interactions in thymic development and function. *Nat Rev Immunol* 2001;1:31-40, copyright 2001.)

self-peptide-MHC complexes so strongly as to be potentially autoimmune. During the final stage of development, CD4+CD8+ T cells suppress the expression of either their CD4 or CD8 coreceptors to give rise to single-positive CD8+ or CD4+ mature thymocytes, respectively. T cells that express MHC class I-restricted TCRs become CD8+ and lymphocytes that express MHC class II-restricted TCRs become positive for the CD4 coreceptor alone. Therefore, along with acting as an environment for T-cell development, the thymus also acts as the principal site of deletion of autoreactive T cells and, as such, shapes the immune repertoire. However, the central thymic elimination of autoreactive T cells is not perfect. Some such cells leak into the periphery, normally becoming subject to complex regulation by peripheral tolerance mechanisms.

T-cell activation

To be activated successfully, T cells require two signals.^{29,30} The first is recognition of antigen by the TCR. On its own, this event can trigger anergy, a nonresponsive state in which T cells are resistant to subsequent activation. T-cell activation requires a second signal delivered by costimulatory molecules expressed on the surface of T cells. The most potent costimulatory signals are delivered when CD28, CD154, or both are ligated on the surface of T cells. Blockade of costimulatory signals by monoclonal antibodies or recombinant receptor antagonists confers potent immunosuppression and allows the acceptance of tissue allografts. Simultaneous blockade of both the CD28 and CD154 pathways is significantly more immunosuppressive than blockade of a single costimulatory pathway. The ligand for CD154 is CD40, a protein expressed on the surface of activated B cells, dendritic cells, and macrophages. The ligands for CD28 (CD80, CD86) are expressed on the surface of APCs such as dendritic cells, monocytes, and B cells. Their expression is induced when APCs are activated in the course of microbial infection. This property heightens the immune response in the setting of perceived danger (e.g., microbial infection). CD80 and CD86 have overlapping immunostimulatory roles; mice lacking either protein are only partially deficient in generating an immune response to foreign antigen.

Following TCR cross-linking, a series of complex intracellular signaling events takes place (see Chapter 14). The early events following TCR cross-linking include activation of Src family kinases Fyn and the CD4/CD8-associated Lck, as well as recruitment of a Syk family kinase, ZAP-70. Activated ZAP-70 phosphorylates LAT, which allows for activation of a set of adapter molecules such as PLC- γ 1, Grb2, and GADS. Numerous downstream molecules then become activated, which leads to cytoskeletal rearrangements; formation of the immune synapse; activation of transcription factors such as ATF-2, NF-AT, NF- κ B, and AP-1; changes in gene expression and expression of numerous cell-surface and secreted proteins; and cell cycle entry.

In unstimulated T cells, TCRs and coreceptors are distributed homogeneously over the T-cell surface. At the synapse between T cells and APCs, however, a large number of receptor-ligand pairs, adhesion molecules, and signaling complexes come together in an organized manner to promote cellular activation.^{31,32} This immunologic synapse is organized so that the TCR, MHC-peptide complexes, and θ -type protein kinase C are enriched in a central circle, surrounded by integrins and intercellular adhesion molecule 1.

The activation signals triggered by TCR ligation are balanced by inhibitory signals that dampen T-cell activation. For example, TCR ligation without CD28 costimulation induces induction of an anergic T-cell state rather than stimulation. Moreover, the inhibitory receptor CTLA-4 competes for the same ligands as CD28 (B7 expressed on APCs) and antagonizes TCR signaling via recruitment of PP2A or SHP-2 phosphatase.³³ The integration of activation and inhibitory signals determines the state of T-cell activation.

T-cell function

Functionally and phenotypically, T lymphocytes are likely the most diverse known population of cells in the human body. A vast amount of data indicates that disturbances in the specific subsets of T cells are directly involved in pathophysiologic mechanisms of autoimmunity and rheumatic diseases.

Cytotoxic T cells

The main function of CD8+ cytotoxic T cells is to induce elimination of “altered-self” cells such as infected or mutated cells. They can also secrete cytokines and participate in regulation (or dysregulation) of immune responses, including in rheumatic diseases. The cytotoxic function is carried out by releasing cytotoxins from lytic granules secreted at the site of target cell contact. These cytotoxins include a family of serine proteases, granzymes A, B, and H, that are capable of inducing caspase-dependent and caspase-independent cell death.³⁴ The role of another secreted cytotoxin, perforin, is to form pores in the target cell membrane and deliver granzymes into the target cell cytosol.^{35,36} Cytotoxic T cells can also trigger cell death through the Fas–Fas ligand pathway. When stimulated through their TCRs, CD8+ T cells transiently upregulate FasL. Subsequent contact with target cells expressing Fas induces apoptotic cell death.

Helper and regulatory T cells

There are several CD4+ helper T-cell (Th) types, based on the cytokines that they produce and the functions that they perform. New T-cell subsets are continually being discovered and characterized.³⁷ Some of the better characterized subsets are shown in Fig. 15.6. Their functions vary broadly: Th1 cells control protection against infection with intracellular microbes, Th2 cells promote humoral immune response necessary to clear parasitic infections, and Th17 cells contribute to autoimmunity and inflammation. Following activation of the immune response and elimination of pathogen, there is a need to downregulate, or suppress, the activity of lymphocytes.^{38,39} Regulatory T cells comprise a subset of peripheral blood CD4+ T cells that express CD25 (a subunit of the interleukin-2 receptor), and transcription factors FOXP3^{40,41} and Helios.^{42,43} They suppress the activity of effector T cells (CD4+CD25–) and inhibit autoimmune processes, ensuring immune tolerance to the body’s own tissues.^{38,39} Numerous subsets of regulatory T cells have already been described, and more subsets are likely to be found in the future.⁴⁴

AUTOIMMUNITY AND TOLERANCE

The advantage of having adaptive immunity is the ability to fend off new, unpredictable pathogens. The prerequisite for such functioning of the adaptive immune system is formation of stochastic repertoires of B- and T-cell specificities, as discussed earlier. However, because newly generated antigen specificities of lymphocytes are random, the numerous emerging lymphocytes are able to react with the own-body molecules as if they were foreign pathogens. In other words, the first target for the adaptive immune system should be the body’s own tissues—the concept of so-called horror autotoxicus. In most cases, this central problem is successfully avoided through a series of regulatory mechanisms that collectively are called *tolerance*. If these mechanisms do not function properly, autoimmunity ensues—a process that is very common in rheumatic diseases. Mechanisms that prevent B cell- or T cell-mediated autoimmune damage are complex but can be separated into central and peripheral mechanisms. Central tolerance is achieved by deletion of high-avidity autoreactive B cells in the bone marrow and autoreactive T cells in the thymus during their maturation, as discussed earlier. The mechanisms that control central tolerance are being vigorously investigated.^{45,46}

Peripheral tolerance is even more complex and diverse. Its mechanisms can be grouped into apoptotic deletion of lymphocytes that are repeatedly stimulated by persistent antigens; anergy of lymphocytes (without deletion) through lack of costimulation, inhibitory signals (such as CTLA-4), or regulatory action of regulatory T cells; immune indifference, or ignorance, due to low avidity of the antigen receptors, low lymphocyte precursor frequency, or low concentration of the antigen; and homeostatic interactions, including immune deviation (switching of cytokine profiles leading to suppression), interclonal competition of lymphocytes for antigen, and idiotype network interactions (antibodies developing against other own-body antibodies). In autoimmune—including rheumatic—diseases, immune tolerance is broken through diverse mechanisms. Such mechanisms may include molecular or

Fig. 15.6 Some of the CD4+ T-cell subsets, with their signature cytokines, hallmark transcription factors driving their differentiation, functions, and related pathologic conditions are shown. DCs, dendritic cells; IFN-γ, interferon-γ; IBD, inflammatory bowel disease; IL, interleukin; Lt-α, lymphotxin-α; MS, multiple sclerosis; RA, rheumatoid arthritis; ROS, reactive oxygen species; TGF-β, transforming growth factor-β; TNF, tumor necrosis factor; Th, helper T cell; Tnaive, naive T cell; Treg, regulatory T cell; Vit A, vitamin. cellular defects weakening central and peripheral tolerance; molecular mimicry (confusion of the adaptive immune system regarding non-self-antigens versus self-antigens); exposure of normally sequestered antigens from immunologically privileged sites; peculiarities of antigen presentation by particular MHC haplotypes; female sex hormones; and various environmental influences. Once the immune tolerance is broken, autoreactive antibodies, T lymphocytes, and circulating immune complexes cause damage to the tissues. The damage may be tissue or organ specific, or systemic, depending on the specifics of a particular disease. In all cases, however, the main cause of autoimmunity is a dysregulation of the adaptive immune system.

CONCLUSION

T and B lymphocytes are the cells of the adaptive immune system. They produce a large repertoire of immunoglobulins and TCRs using somatic

gene recombination. Clonal selection preserves those cells whose products prove useful in fighting off pathogens. Specialized helper T cells such as Th1, Th2, or Th17 produce characteristic cytokines that divide immune responses into several distinct types. There is an intrinsic risk of autoimmunity built into the adaptive immune system that is the cost of generating virtually unlimited repertoires of immune specificities. The potential of the adaptive immune system to induce autoimmunity is usually controlled by a combination of deletional and regulatory tolerance mechanisms. Regulatory T cells play a central role in maintaining immune tolerance. Failure of tolerance leads to autoimmunity, in which the immune system attacks its own tissues. Autoimmunity commonly occurs in and contributes to mechanisms of rheumatic diseases. By its nature, the adaptive immune system potentially represents the most specific target for therapy in autoimmune diseases. As our understanding of immune function at the cellular and molecular levels increases, we may soon be in a position to modulate the immune response for the benefit of patients with autoimmune rheumatic disease.

Principles of innate immunity

■ TSUNEYASU KAISHO ■ SHIZUO AKIRA

- Innate immunity senses and responds to a variety of microorganism- or host-derived molecules.
- Innate immune sensors are functionally categorized into three classes: signaling, internalizing, and soluble sensors.
- Signaling sensors, such as Toll-like receptors, trigger signaling pathways for activating immune response genes.
- Internalizing sensors incorporate microorganisms and degrade or process them for presentation to T cells.
- Soluble sensors opsonize microorganisms, thus marking them for internalization, and activate protease cascades.
- Innate immunity induces inflammation, triggers adaptive immune responses, and provokes antiviral immunity.
- Innate immune sensors are involved in the pathogenesis of not only infectious and autoimmune diseases but also various inflammatory conditions in metabolic diseases.

INTRODUCTION

Host defense consists of two types of immunity: innate and adaptive immunity (Table 16.1). Adaptive immunity is found only in jawed vertebrates and is mediated by B and T lymphocytes. These cells possess the RAG genes that mediate a somatic recombination system and thereby create a large repertoire of antigen receptors. Antigen receptors with certain specificity are clonally expressed, and, owing to allelic exclusion, each lymphocyte bears only one antigen receptor. Thus groups of lymphocytes are highly heterogeneous in terms of antigen specificity. During the immune response, receptors with high affinity for an invading antigen are clonally selected, and lymphocytes bearing such receptors later stay on as memory cells.

Although this defense system is highly beneficial for the host, to establish adaptive immunity and to mount an adaptive immune response takes time. Especially early in the course of an infection, an immediate response is required for efficient host defense. This immediate response is mediated by innate immunity. Innate immunity is an evolutionarily ancient system that is found in all multicellular organisms, including plants and insects. In mammals, innate immunity depends on macrophages or dendritic cells (DCs), which do not possess rearranged receptors. Insects can develop resistance to infection, which indicates that innate immunity is sufficient to eradicate pathogens effectively. In contrast to adaptive immunity, innate immunity is mediated by a group of germline-encoded receptors with a fairly limited repertoire of antigen receptors. Those innate immune sensors can recognize various molecular structures derived from microorganisms, which can be referred as *pathogen- or microorganism-associated molecular patterns*.¹ They are called *microorganism-associated molecular patterns* (MAMPs) hereafter because such structures are found irrespective of pathogenicity. Unlike rearranged antigen receptors in the adaptive immune system, any given innate immune sensor is expressed on a variety of innate immune cells, and each cell possesses a combination of several sensors. Therefore innate immune cells are simultaneously or sequentially activated through a variety of sensors. Importantly, innate immune sensors also recognize host-derived endogenous molecules, called *danger/damage-associated molecular patterns* (DAMPs), and are involved in a variety of noninfectious inflammatory conditions. This chapter discusses the innate immune system as a sensor system for activating immune or inflammation responses.

SENSING BY INNATE IMMUNITY

Innate immune sensors can be functionally divided into three categories: signaling, internalizing, and soluble sensors (Fig. 16.1).

Signaling sensors

Signaling sensors are expressed on the cell surface, in the endosome, or in the cytosol, where they recognize their corresponding ligands. On recognition, these sensors can stimulate signaling pathways leading to activation of various signaling molecules, such as nuclear factor κ B (NF- κ B) or mitogen-activated protein kinases (MAPKs). This then leads to expression of a variety of immune response genes, including inflammatory cytokines or costimulatory molecules such as CD40 and CD86.

Toll-like receptors

The Toll-like receptor (TLR) family is a group of typical signaling sensors.^{2,3} TLRs are expressed on the plasma membrane or in the endosome and play major roles in activating antigen-presenting cells (APCs). TLRs are type I transmembrane proteins. Their extracellular domain includes a repetitive structure rich in leucine residues, called *leucine-rich repeat* (LRR), that is involved in the recognition of a variety of TLR ligands. The intracellular region contains a common structure in TLR and interleukin-1 receptor (IL-1R) family members called *Toll/IL-1R homologous* (TIR) domain that is essential for signal transduction through TLRs.

TLRs can recognize a variety of MAMPs. TLR ligands can be categorized as lipid, protein, and nucleic acid components (Fig. 16.2). Phylogenetically related TLRs can recognize similar types of ligands. All TLR ligands are potent immune adjuvants that can trigger a vigorous immune response. The most widely investigated TLR ligand is lipopolysaccharide (LPS).⁴ LPS is found in the outer cell walls of gram-negative bacteria and is recognized by TLR4. LPS is first bound to a soluble factor, LPS-binding protein, in the serum and transferred to target cells such as macrophages. Macrophages express a phosphatidylinositol-anchored cell surface molecule, CD14, which can capture and retain LPS. LPS then activates TLR4. A small secreted molecule, myeloid differentiation factor 2 (MD-2), is associated with TLR4 and critically involved in forming an LPS-recognizing complex.⁵

Other lipid-containing components of cell walls of a variety of microorganisms are recognized by TLR2 and related TLRs, such as TLR1 and TLR6. Heterodimerization is critical for TLR2-mediated recognition. For example, TLR2 can recognize mycoplasma macrophage-activating lipopeptide 2 (MALP-2) when associated with TLR6. Meanwhile, a TLR2-TLR1 heterodimer is involved in recognizing bacterial lipopeptides. MALP-2 and bacterial lipopeptides carry a diacylated and triacylated cysteine residue at their N-terminals, respectively, and this subtle difference is discriminated by TLR2-containing heterodimers.

TLR5 is involved in recognizing a protein, flagellin, that is a component of the bacterial flagella used for propulsion in a liquid medium. Flagellin can elicit mucosal immune responses by acting on epithelial cells or macrophages. Although flagellin is a protein, its amino acid structure is highly conserved, which suggests that it is a target for innate immune recognition.

Nucleic acids are equally important MAMPs recognized by TLRs. Bacterial DNA has long been known to be a strong immune adjuvant.⁶⁻⁸ This adjuvant activity depends on an unmethylated CpG (cytosine phosphate guanine) motif. The CpG motif is more abundant in bacterial DNA than in mammalian DNA. Furthermore, mammalian CpG DNA is often methylated. Therefore unmethylated CpG DNA can be regarded as nonself and is recognized by TLR9. Viral DNA is also rich in the CpG motif, and DNA virus infection does indeed trigger TLR9 signaling.

TABLE 16.1

Innate and adaptive immunity

	Innate immunity	Adaptive immunity
Evolution	Ancient	Jawed vertebrates or higher
Cells	Macrophages Dendritic cells (Antigen-presenting cells)	T and B lymphocytes
Receptors	Encoded in germline Limited repertoire Nonclonal	Created by rearrangement Large repertoire Clonal expression
Memory	No	Yes
Ligands	Molecular structures conserved in a group of microorganisms (MAMPs; e.g., LPS, CpG DNA), host-derived damaged molecules (DAMPs)	Fine structures (peptides)
Responses	Immediate	Slow

CpG, cytosine phosphate guanine; DAMPs, danger/damage-associated molecular patterns; LPS, lipopolysaccharide; MAMPs, microorganism-associated molecular patterns.

Fig. 16.1 Signaling sensors trigger signal transduction pathways upon recognition. Internalizing sensors directly incorporate microbes into the cell. Soluble sensors attach to the microbes and support the function of internalizing sensors. Soluble sensors also activate protease cascades. Ag, antigen; MHC, major histocompatibility complex; TLR, Toll-like receptor.

Several small synthetic molecules, including imidazoquinoline derivatives and several anticancer drugs, have long been known for their antiviral activity. This activity depends on TLR7. Single-stranded RNA (ssRNA) from influenza or human immunodeficiency virus is also a ligand for TLR7 and its close relative, TLR8. This interaction is critical for sensing RNA virus infection. RNA virus infection also induces the production of double-stranded RNA (dsRNA) in infected cells, and these dsRNAs can act as immune adjuvants and are recognized by TLR3.

TLRs can also recognize DAMPs. DAMPs are host-derived endogenous molecules, hidden within cells and ignored by the immune system in the steady state. After tissue damage or cell death, they are released and detected by the innate immune sensors. Nucleic acids are typical DAMPs and are recognized by TLR3, TLR7, TLR8 and TLR9. These TLRs fail to distinguish between microorganism- and host-derived nucleic acids (see later). RNAs damaged by ultraviolet radiation or mitochondrial DNA are sensed by TLR3 and TLR9, respectively. TLR4 also recognizes a variety of DAMPs. These include not only lipids such as saturated fatty acids or oxidized low-density lipoprotein cholesterol but also proteins such as heat shock proteins or S100 family proteins.

Fig. 16.2 The phylogenetic relationships of the human Toll-like receptors (TLRs) are shown by the dotted lines based on an analysis of their amino acid structures. Branch lengths are proportional to evolutionary distances. CpG, cytosine phosphate guanine; dsRNA, double-stranded RNA; LPS, lipopolysaccharide; ssRNA, single-stranded RNA.

Importantly, TLR2 and TLR4 are expressed mainly on the plasma membrane, whereas nucleic acid-recognizing TLRs are expressed in the endoplasmic reticulum. Upon activation, chaperone molecules such as UNC93B1 escort nucleic acid-recognizing TLRs to the endosome, where nucleic acids are released from virus or virally infected cells. Thus lipid and nucleic acid TLR ligands are recognized in distinct cellular compartments.

Cytosolic signaling sensors

Signaling sensors also exist in the cytosol. DExD/H-box helicase family members, which are characterized by motifs that include the DExD/H amino acid sequence (D, E, x, and H represent aspartic acid, glutamic acid, any amino acid and histidine, respectively) and are highly conserved throughout species, function as cytosolic sensors for a variety of nucleic acids, mainly from microorganisms including viruses. The representative members are retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs) such as RIG-I and melanoma differentiation-associated gene 5 (MDA5).^{9,10} RIG-I and MDA5 carry tandem caspase recruitment domains (CARDs) and an RNA helicase domain at the N-terminal and C-terminal, respectively, and the RNA helicase domain is involved in recognizing the ligands. Both RIG-I and MDA5 can recognize virally derived RNAs, but they sense distinct molecular structures and play differential roles in viral infection.¹⁰ For example, RIG-I is essential for recognizing various ssRNA viruses, including paramyxoviruses, influenza virus A, and Japanese encephalitis virus, whereas MDA5 is critical for sensing picornaviruses. RIG-I can recognize 5'-triphosphate ssRNA, which is a typical structure found in viral, nonself RNA. Host-derived self-RNA, on the other hand, has a cap structure to mask 5'-triphosphate RNA. Thus RIG-I can distinguish viral RNA from self-RNA.

Several other DExD/H-box helicases are also involved in sensing nucleic acids.¹¹ DDX3 and DDX60 bind to viral RNA. DDX1, DDX21, and DHX36 also recognize viral dsRNA. Furthermore, DDX41 recognizes double-stranded DNA (dsDNA). These sensors play their specific roles in diverse cell types.

Nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) also are cytosolic sensors (Fig. 16.3).¹² NLRs consist of more than 20 members in humans and mice. They carry a CARD, a pyrin domain, or a baculoviral inhibitor of apoptosis repeat (BIR) domain as a protein interaction domain at the N-terminal, which is followed by a NACHT nucleotide-binding domain (NBD) and an LRR domain. NOD1 and NOD2 are representative NLR members involved in recognizing bacterial peptidoglycan-derived molecules.¹³ NLR family apoptosis inhibitory protein 5 (NAIP5) can sense flagellin derived from intracellular bacteria such as *Salmonella* or *Legionella*. An NAIP5-related molecule, NAIP2, can detect conserved rod proteins of the type III secretion system from *Salmonella* or *Burkholderia*. Notably, NLR family pyrin domain-containing 3 (NLRP3) is required for responses against a variety of MAMPs and DAMPs. These include bacterial

Fig. 16.3 Nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) are cytosolic signaling sensors and recognize a variety of microorganism-associated and danger/damage-associated molecular patterns. Importantly, NLRs can activate inflammasome and induce production of active interleukin- β 1 (IL-1 β) and IL-18. ATP, adenosine 5'-triphosphate; DAMPs, danger/damage-associated molecular patterns; dsDNA, double-stranded DNA; IL, interleukin; TTSS, type III secretion system.

products such as RNA or toxin, host-derived nucleic acid metabolites such as adenosine 5'-triphosphate, uric acids, and oxidized mitochondrial DNA. Furthermore, environmental substances such as silica crystals or asbestos and a widely used chemical immune adjuvant, alum, can also activate NLRP3-mediated signaling.

Members of the pyrin and hematopoietic interferon-inducible nuclear (HIN) domain-containing protein (PYHIN) family also function as cytosolic sensors. This family carries an N-terminal pyrin domain and two DNA-binding HIN domains. Both absent in melanoma 2 (AIM2) and interferon- γ -inducible protein 16 (IFI16) belong to this family and are involved in detecting dsDNA.

Internalizing sensors

Internalizing sensors are expressed on the surface of neutrophils, macrophages, or DCs. They bind to and internalize MAMPs or microorganisms, which are subsequently transported to lysosomal compartments (see Fig. 16.1). This process is termed *phagocytosis*, and the group of sensors involved can thus also be referred to as *phagocytic sensors*.¹⁴ After phagocytosis, organism-derived proteins are degraded or processed for presentation to T cells. Internalizing sensors mainly function to incorporate the organisms or their components, but some internalizing sensors can also transduce the activation signals.

Lectin

Lectins generically represent carbohydrate-recognizing proteins, and some lectins function as internalizing sensors. The mannose receptor is a type I transmembrane protein that can bind terminal mannose and fucose residues of glycoproteins or glycolipids, which are found on microbial cell walls. The macrophage scavenger receptor SR-A is a type II transmembrane protein. Although originally defined by its ability to bind and mediate endocytosis of oxidized or acetylated low-density lipoprotein, it can also bind a variety of microorganisms. Macrophage receptor with collagenous structure (MARCO) is structurally and functionally similar to SR-A and can bind to gram-positive and gram-negative bacteria.

Dectin-1 is a C-type lectin and is involved in recognizing β -1,3-linked or β -1,6-linked glucans found in fungal or other microbial cell walls. Dectin-1 carries an immunoreceptor tyrosine-based activation motif (ITAM) in the intracytoplasmic region and also functions as a signaling sensor. Dectin-1 is colocalized with TLR2 in the phagosome and activates macrophages in synergy with TLR2. Macrophage-inducible C-type lectin (Mincle) also carries an ITAM and can induce macrophage activation by sensing a mycobacterial glycolipid, trehalose-6,6'-dimycolate, also called *cord factor*. Mincle also detects a nuclear ribonucleoprotein that belongs to the DAMP

Fig. 16.4 Mammalian Toll-like receptors (TLRs) directly recognize microbial components, whereas *Drosophila* Toll detects a host-derived molecule. In *Drosophila*, microbes are discriminated by soluble factors in the hemolymph, which leads to the activation of protease cascades.

group. Another ITAM-carrying C-type lectin, CLEC9A, also known as *DNGR-1*, senses exposed actin filaments, which also are DAMPs.

Soluble sensors

Soluble sensors are produced by macrophages or hepatocytes and bind to the cell wall of microorganisms, thus designating them as targets for phagocytosis (see Fig. 16.1). This coating process is termed *opsonization*, and the coating substances are called *opsonins*. The serum levels of certain soluble sensors, such as C-reactive protein and serum amyloid P component, increase in response to inflammatory cytokines; therefore, these sensors are also referred to as *acute-phase proteins*.¹⁵ Soluble sensors are linked to the complement system and can activate protein cascades that are capable of eradicating pathogenic microbes.

Complement system

The complement system consists of more than 35 soluble or membrane proteins (see Chapter 20).¹⁶ Microbial infection activates three distinct pathways—the classical, alternative, and lectin pathways—for complement activation. All pathways activate a common pathway that involves cleavage of C3 into C3a and C3b. C3b attaches to the microbial surface, and microbes opsonized by C3b are then eliminated by phagocytosis or killed by membrane attack complex.

PHYLOGENETIC COMPARISON OF THE RECOGNITION SYSTEM

Toll-like receptors have been so named because their molecular structure is similar to that of *Drosophila* Toll.^{17,18} Toll is a type I transmembrane protein carrying an LRR repeat and a TIR domain. Toll-deficient flies display increased susceptibility to fungal infection, which indicates that Toll is essential for antifungal immunity in insects. Furthermore, both Toll and TLRs can activate signaling pathways leading to the release of antimicrobial substances.

The *Drosophila* Toll system, however, is distinct from the mammalian TLR system (Fig. 16.4). Toll does not directly recognize fungi-derived products. The pathogens are recognized by certain still-unidentified soluble factors. In fungal infection, protease cascades are activated to induce cleavage of a secreted protein, Spätzle. Processed Spätzle then binds to Toll. Thus Toll recognizes a host-derived product.

Toll is also involved in immunity against gram-positive bacteria.¹⁹ A soluble molecule, peptidoglycan recognition protein SA (PGRP-SA), recognizes peptidoglycans from bacteria, which leads to activation of protease cascades that also cleave Spätzle. PGRP-SA-deficient flies are susceptible to infection with gram-positive bacteria but retain immune responses against

Fig. 16.5 Macrophages or dendritic cells (DCs) detect invasion of microorganisms through innate immune sensors and produce chemokines or cytokines, thereby inducing inflammatory reactions. Activated DCs migrate into lymph nodes and provoke T-cell activation.

fungi, whereas Toll-deficient flies succumb to infection with both organisms. This indicates that the discrimination of fungi and bacteria happens upstream of Toll. Thus flies detect pathogens in the hemolymph, not on the plasma membrane. In mammals, the complement system, rather than the TLR system, is similar to Toll when one considers recognition in the fluid and activation of protease cascades.

CRITICAL FUNCTIONS OF INNATE IMMUNITY

Induction of inflammation

Innate immunity detects microbial infection and induces inflammatory reactions in local peripheral tissues such as the skin (Fig. 16.5). TLRs expressed on macrophages or DCs play major roles in this process. TLR signaling can induce robust production of proinflammatory cytokines including IL-6 and tumor necrosis factor- α (TNF- α), chemokines, and adhesion molecules and thereby recruit or activate various inflammatory cells at the sites of infection. Recruited and activated macrophages or neutrophils then ingest, through internalizing sensors, and subsequently kill invading pathogens by producing nitric oxide, reactive oxygen species, or defensins. NLR signaling can induce generation of proinflammatory cytokines such as IL-1 β and IL-18 through the activation of inflammasome (see later) and contributes to inflammatory reactions. Inflammation is a critical local response to resolve infection. However, inflammation is a double-edged sword, because excessive amounts of cytokines can be lethal for the host, as is the case in endotoxin shock.

Activation of adaptive immunity on infection

Locally activated APCs mature to express a distinct set of chemokine receptors. Then they are transported to the lymph nodes, where they interact with and activate T cells (see Fig. 16.5). Thus an innate immune response subsequently leads to the activation and establishment of adaptive immunity. Clonal T-cell expansion requires not only T-cell receptor-mediated but also costimulatory molecule-mediated signaling (Fig. 16.6). Internalizing sensors facilitate antigen presentation, and signaling sensors such as TLRs can enhance expression of costimulatory molecules, including CD80 and CD86. Thus innate immune sensors directly contribute to the activation of adaptive immunity.

A CD4⁺ T cell differentiates into a type 1 helper T (Th1), type 17 helper T (Th17), or type 2 helper T (Th2) cells.²⁰ Th1 cells produce interferon- γ (IFN- γ) and mediate antiviral or antibacterial immunity. Th17 cells produce IL-17 and are involved not only in antibacterial immunity but also in various inflammatory conditions such as autoimmune disorders. Th2 cells secrete IL-4 or IL-13 and are involved in immunity against helminths, but excessive

Fig. 16.6 Activated dendritic cells (DCs) induce proliferation of antigen-specific T cells and instruct them in differentiating into type 1 helper T (Th1), Th2, or Th17 cells depending on the DC activation stimuli. Ag, antigen; IFN- γ , interferon- γ ; IL, interleukin; TCR, T-cell receptor; TGF- β , transforming growth factor- β ; TLR, Toll-like receptor.

activation of these cells may cause allergic reaction. APCs are critically involved in regulating Th cell differentiation. This activity depends on tissue origin, cell subsets, or maturation stage of the APCs. But the nature of the stimuli activating the APCs is most important. Most TLR ligands can activate APCs to produce Th1- or Th17-inducing cytokines such as IL-12, IL-18, IL-6, or IL-23. Although Th2-inducing sensors are not well characterized yet, certain helminths or their products can enhance the ability of APCs to support Th2 cell differentiation.

Antiviral responses

Innate immunity responds to viral infection by producing type I IFNs.²¹ Type I IFNs consist of more than 10 IFN- α proteins and a single IFN- β protein. However, all type I IFNs use IFN- α/β receptor (IFNAR), composed of IFNAR1 and IFNAR2 subunits, as a common receptor. The signaling can induce expression of a number of antiviral molecules including 2'-5'-oligoadenylate synthases or IFNs themselves. It can also upregulate expression of the major histocompatibility complex (MHC) and induce DC maturation. These effects contribute to antiviral immune responses.

Type I IFN production is triggered by innate immune signaling sensors. Cytosolic sensors such as RLRs are potent type I IFN-inducing sensors and are expressed in a variety of cells, including macrophages and fibroblasts. Among TLRs, TLR7 and TLR9 can induce both IFN- α and IFN- β . The other TLRs, except TLR3 and TLR4, fail to induce type I IFNs. TLR3 and TLR4 can induce only IFN- β but not IFN- α . TLR4-induced IFN- β plays a critical role in shock induction and bacterial infection, but, as a principle, in viral infection TLRs that recognize nucleic acids are more critical than TLR4 in production of type I IFNs.

Plasmacytoid dendritic cells (PDCs) are a DC subset and also are known as IFN- α -producing cells.²² PDCs look like plasma cells and exhibit poor antigen-presenting activity owing to low levels of expression of MHC class II and costimulatory molecules. PDCs express TLR7 and TLR9 exclusively among TLRs and are involved in antiviral immunity by secreting copious amounts of type I IFNs, especially IFN- α , in a TLR7/9-dependent manner.

Cross-presentation is also important in antiviral immunity.²³ Cross-presentation is defined as exogenous antigen presentation through MHC class I to generate CD8⁺ T-cell responses (Fig. 16.7). Virally infected cells are ingested by APCs. Antigens are processed and transported to MHC class II-containing endolysosomes, where antigens associate with MHC class II molecules. The antigen-MHC class II complex then becomes competent for presentation to CD4⁺ T cells. Exogenous antigens can also be subjected to the association with MHC class I. Antigens can be transported to the cytosol, processed by proteasomes, and then incorporated into the endoplasmic reticulum in a transporter associated with antigen processing (TAP)-dependent manner. Then antigens bind to MHC class I molecules and are presented to CD8⁺ T cells. Alternatively, antigens can be transferred

Fig. 16.7 Virally infected cells are incorporated into antigen-presenting cells, and antigens are presented with major histocompatibility complex (MHC) class I or class II molecules. Toll-like receptors (TLRs) can promote cross-presentation, which depends on MHC class I. TAP, transporter associated with antigen processing.

directly to the MHC class I-containing compartment, not via the cytosol. The cross-presentation system ensures that virally infected cells, which do not always possess the ability to present antigen by themselves, can be targets for cytotoxicity. Cross-presentation also should be critical in cancer surveillance, because most cancer cells show poor antigen presentation ability. Several immune sensors such as TLRs can facilitate the cross-presentation, and one DC subset defined by the presence of CD8 α , CD103, or the chemokine receptor XCR1 features a high ability to phagocytose dying cells and cross-present the antigens.²³

MOLECULAR MECHANISM OF SENSOR SIGNALING

TLR carries the intracytoplasmic TIR region.²⁴ This region associates with cytoplasmic adapters that also possess the TIR region. This association is critically involved in stimulating various pathways leading to activation of NF- κ B or interferon regulatory factors (IRFs). There are five TIR domain-containing adapters, and four of them—myeloid differentiation primary response gene 88 (MyD88), TIR domain-containing adapter protein (TIRAP)/MyD88-adaptor-like (MAL), TIR domain-containing adapter protein-inducing IFN- β (TRIF), and TRIF-related adapter molecule (TRAM)—are involved in the pleiotropic function of TLRs (Figs. 16.8 and 16.9). MyD88, characterized first among the TLR adapters, associates with all TLRs except TLR3. MyD88 is essential for TLR-induced cytokine production. TIRAP cooperates with MyD88 downstream of TLR2 and TLR4. MyD88 is critical for all TLR7/9-induced effects, including type I IFN induction (see Fig. 16.9). Meanwhile, TRIF, but not MyD88, is essential for TLR3- or TLR4-induced type I IFN production (see Fig. 16.8). TRAM is required for TLR4 to associate with TRIF. TLR3 can directly associate with TRIF and does not require TRAM for its signaling. Notably, the MyD88-TIRAP and TRIF-TRAM pathways are initiated at the plasma membrane and endosome, respectively. These adapters differentially stimulate signaling cascades that involve IL-1R-associated kinases (IRAKs) or an adapter molecule, tumor necrosis factor receptor-associated factor 6 (TRAF6), and induce the activation of various transcription factors. Activation and nuclear translocation of NF- κ B, IRF-3, and IRF-7 can cause gene expression of proinflammatory cytokines and type I IFNs (see Figs. 16.8 and 16.9).

Inhibitor of κ B kinase (IKK) family members play critical roles in linking TLR signaling and activation of transcription factors (see Figs. 16.8 and 16.9). NF- κ B activation depends on IKK β . IRF-3 activation is induced by a heterodimer of IKK κ /t and TANK-binding kinase 1 (TBK1). The TLR7/9 signaling mechanism in PDCs is peculiar in that the MyD88-mediated pathway leads to IRF-7 activation via IKK α and interleukin-1 receptor-associated kinase 1 (IRAK1).

Fig. 16.8 Toll-like receptor 2 (TLR2), TLR3, and TLR4 can induce production of proinflammatory cytokines. TLR3 and TLR4 can also induce production of interferon- β but not of IFN- α . MyD88 is critical for TLR2/4-induced production of proinflammatory cytokines, whereas TRIF (TIR domain-containing adapter protein inducing IFN- β) is required for TLR3/4-induced production of IFN- β . In TLR3/4 signaling, TRIF also contributes to induction of proinflammatory cytokines. IL, interleukin; TNF, tumor necrosis factor.

Fig. 16.9 Cytosolic sensors and Toll-like receptors 7 and 9 (TLR7/9) have potent ability to induce type I interferons (IFNs), including IFN- α and IFN- β , as well as proinflammatory cytokines. The TLR7/9-induced type I IFN induction pathway functions mainly in plasmacytoid dendritic cells. IL, interleukin; RLR, retinoic acid-inducible gene I (RIG-I)-like receptors; TNF, tumor necrosis factor.

RLRs do not use adapters with the TIR region but require a CARD-like domain-carrying adapter, IFN- β promoter stimulator 1 (IPS-1; also known as CARD adapter-inducing IFN- β [Cardif], mitochondrial antiviral signaling [MAVS], or virus-induced signaling adapter [VISA]) (see Fig. 16.9). IPS-1 can induce production of proinflammatory cytokines and type I IFNs through the activation of NF- κ B and IRF-3/7 via IKK β and IKK κ /t-TBK1, respectively. The TLR3/4-mediated pathway also converges this cascade by activating IKK β and IKK κ /t-TBK1 complex via TRIF, but not via IPS-1 (see Fig. 16.8). Some cytosolic sensors such as DDX41 and IFI16 activate TBK1 and induce type I IFNs through the association with stimulator of IFN genes (STING).

Inflammasome is a molecular platform that is activated mainly by NLRs (see Fig. 16.3).^{25,26} Inflammasome is activated in several ways, depending

on NLRs or NLR-related molecules such as NLRP3, NAIP5, NAIP2, NLRP1, or AIM2. Each inflammasome requires apoptosis-associated specklike protein containing a caspase activation and recruitment domain (ASC, also known as *pyrin domain and CARD domain containing* [PYCARD]) or NLR family CARD domain-containing 4 (NLRC4) as a CARD-containing molecule. ASC and NLRC4 are critically involved in recruiting caspase-1, which can convert pro-IL-1 β and pro-IL-18 to biologically active cytokines IL-1 β and IL-18, respectively.

SENSORS AND DISEASES

Toll-like receptors and autoimmunity

As noted earlier, nucleic acid-sensing TLRs cannot distinguish between host- and microorganism-derived nucleic acids. Unmethylated CpG motifs, which are TLR9 ligands, and ssRNA, which is a TLR7 ligand, can be found in the host. Host cells are phagocytosed after they die, and nucleic acids from ingested cells are then released to endosomes or phagosomes. Thus hosts potentially expose themselves to the risk of an autoimmune response. However, this risk is contained by several factors. First, these nucleic acids are very unstable and easily degraded. Second, TLR7 and TLR9 are expressed in the endosome or endoplasmic reticulum and segregated from nucleic acids released in the serum. Furthermore, the host possesses some DNA sequences that can inhibit TLR9 signaling.²⁷ Such sequences can be found in the telomere. Thus several fail-safe mechanisms prevent unwanted adjunct effects of host-derived nucleic acids.

The break of this tolerance seems to contribute to the pathogenesis of certain autoimmune diseases, such as systemic lupus erythematosus (SLE).²² In SLE, anti-nucleic acid antibodies are produced, and immune complexes containing nucleic acids are retained as a stabilized form in the serum. The immune complexes are then incorporated into and activate PDCs to produce type I IFNs by coengaging TLRs and Fc receptors. In addition to anti-nucleic acid antibodies, endogenous proteins also can bring out the autoimmune potential of host-derived nucleic acids. Upon massive cell necrosis, nuclear proteins such as high-mobility group box 1 (HMGB1) are released. These proteins bind nucleic acids and facilitate TLR9-induced immunostimulatory effects. One of these, the cationic antimicrobial protein LL37, can also form a complex with DNA. This complex formation facilitates the incorporation of DNA by PDCs and its retention in the early endosome, which thereby activates the PDCs to produce type I IFNs via TLR9. Production of LL37 is elevated in the skin lesions of persons with psoriasis.²⁸ Chromatin proteins and LL37 are included in neutrophil extracellular traps (NETs), which are released from neutrophils. NETs were originally identified as the mechanisms for killing invading microorganisms, but accumulating evidences suggest that NETs are also involved in the pathogenesis of autoimmune diseases.²⁹ Thus not only anti-nucleic acid antibodies but also endogenous molecules contribute to bypassing the fail-safe mechanisms that would normally block the immunopathologic potential of TLR7/9 signaling (Fig. 16.10).

Rheumatoid factor (RF) is an immunoglobulin that can bind to certain types of immunoglobulin G and is often found in the sera of patients with autoimmune disorders. Immune complexes containing nucleic acids can activate RF+ B cells by dual engagement of a B-cell receptor and TLR9.³⁰ Thus TLR signaling is critically involved in both PDC and B-cell activation in autoimmunity.

Toll-like receptors and metabolic diseases

Innate immune sensors also play major roles in the pathogenesis of metabolic diseases that so far have been considered to be nonimmunologic diseases. During the course of obesity, adipocytes secrete chemotactic factors and recruit macrophages. Adipocytes also produce saturated fatty acids, which activate recruited macrophages via TLR4 to produce TNF- α . TNF- α then further activates adipocytes to produce saturated fatty acids. Thus obesity is associated with a low-grade chronic inflammation caused by the loop between adipocytes and macrophages.³¹ Furthermore, mitochondrial DNA can cause myocarditis and dilated cardiomyopathy when it escapes degradation by autophagy.³² TLR9 is required for induction of this inflammatory state leading to heart failure.

Fig. 16.10 Viral and self nucleic acids activate dendritic cells (DCs) through Toll-like receptors 7 and 9 (TLR7/9). Virus or virally infected cells are incorporated and viral nucleic acids are released in the endosome, where nucleic acid-recognizing TLRs are localized. Self nucleic acids also gain access to the endosome through the association with anti-nucleic acid antibodies, rheumatoid factor (RF), nuclear proteins, or antimicrobial peptides. On binding of TLR9 to its ligand, the extracellular domain of TLR9 is cleaved to be activated. Ab, antibody; FcR, Fc receptor; RF, rheumatoid factor.

NOD-like receptors and inflammation

Excessive activation of the inflammasome can provoke various inflammatory conditions. Hyperuricemia leads to precipitation of uric acid crystals (monosodium urate) in the joints and causes gout arthritis through NLRP3 activation. Pneumoconiosis is a pulmonary inflammatory disease induced by long-term inhalation of particulate dust such as asbestos or silica, which can activate the NLRP3 inflammasome. Furthermore, autosomal dominant mutations in NLRP3 are associated with a group of autoinflammatory disorders that include familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and neonatal-onset multisystemic inflammatory disease. Clinical symptoms of these diseases include recurring episodes of fever, rash, and arthropathy. Notably, these manifestations are ameliorated by treatment with an IL-1R antagonist (see Chapter 165).

CONCLUSION

The innate immune system efficiently uses a combination of signaling, internalization, and soluble sensors to establish host defense. Intense research over the past few years has led to the clarification of the basic molecular mechanism of innate immunity, and several clinical applications that target innate immune receptors are now in development. Notably, innate immune sensors detect not only MAMPs but also DAMPs, and their recognition of DAMPs contributes to the pathogenesis of various metabolic disorders that have not been considered to be immunologic diseases. Therefore further understanding of how innate immune cells function may potentially lead to the development of new treatment strategies for a variety of disease conditions beyond the immune disorders.

ACKNOWLEDGMENTS

The authors thank all the colleagues in their laboratory for helpful discussions and Yoshiko Matsuhisa for secretarial assistance. This work was supported by the Kishimoto Foundation, the Ministry of Education, Culture, Sports, Science, and Technology (MEXT), and the Japan Society for the Promotion of Science.

Systems biology

■ ANGELA BAUCH ■ GIULIO SUPERTI-FURGA

- Analyses at the systems level deal with emergent properties of normal (healthy) and abnormal (pathologic) systems resulting from the interplay of all their molecular components. The advent of systems biology and the knowledge from systems-level studies on inflammatory processes can uncover complex molecular mechanisms and foster innovative patient- or group-specific treatments.
- Integration of technologies and data types is imperative for systems approaches to gain holistic insights into networks and whole biologic systems. At the same time it represents a serious challenge that must be addressed not only by information technology solutions but also by significant methodologic and cultural changes in the investigational approaches of the scientific and medical communities.
- Reconstruction of signaling and transcriptional networks enhances the understanding of biologic systems. Superposition of computational methods associating specific network behaviors with genomic makeups and downstream clinical outcomes will enable genome-informed diagnostics and identify therapeutic approaches using single agents or combinations of agents that correct network malfunctions.

INTRODUCTION

This chapter discusses systems biology and associated technologies and focuses on answering the following two questions:

1. Can the molecular processes underlying inflammation be characterized in a comprehensive fashion?
2. Would such characterizations go beyond the descriptive surface and reveal insights into disease mechanisms that could inform diagnosis or choice of therapy?

Genomics, transcriptomics, proteomics, metabolomics, and any other “-omics” approaches should be of interest to the rheumatology scholar because they represent global and systematic, as opposed to focused or anecdotal, molecular descriptions of a healthy or pathologic process in biology (Fig. 17.1). These “-omics” perspectives, which can be grouped as elements of what is collectively termed *systems biology*, stem from recognition that knowledge of the human and other genomes obliges us to consider the roles of all possible molecular players in the process under investigation, and not just the role of individual genes and gene products.

WHAT IS SYSTEMS BIOLOGY?

Systems biology aims at understanding biologic and pathologic processes as integrated entities. This requires understanding the properties of the entire system from the whole molecular pathway through to the target organelle, cell, organ, and ultimately the whole body—a sort of bird’s-eye view or wiring plan. The analogy to a car engine can be useful here. For example, consider dealing with individual engine parts, such as a spark plug. With this approach, the spark plug is discovered to be essential for the engine to start, but relatively little is understood beyond that. The first rough assembly of the human genome sequence published in the year 2000 allowed us access to a more complete “parts list” (i.e., the genome). Other parts lists (e.g., the proteome) have since followed, delivered by “-omics” technologies. Yet systems are more than the sum of their parts. Their properties are

a consequence of the interplay of their elements. Thus, to fully understand an engine in its entirety, the assembly plan as well as a model of how the engine works is needed. Using this analogy, therefore, one could include what fuels it, what sort of performance can be expected, and what is the waste it generates. This higher-level understanding is the essence of systems biology. It involves quantitation as well as networks and mathematical modeling, as discussed below. This makes systems biology very different from the analysis of single elements of a system and represents a great challenge for investigators. Physiology has traditionally been the biomedical area in which the function of the body parts has been investigated in the context of the next level of organization (cells within organs within bodies) to determine interdependencies and higher-order function. For most purposes, it is fair to consider systems biology a modern, molecularly savvy type of traditional physiology that takes for granted a knowledge of the tiniest building blocks of individuality, the genes in the genomes.

EXAMPLE OF SYSTEMS BIOLOGY IN PRACTICE

An early example of how such a systems-level perspective can help us understand the underlying principles of entire systems involves the analysis of genes regulated by serum. For the two decades preceding the new millennium, scientists studied serum-stimulated gene-regulatory elements of individual genes, such as the c-Fos transcription factor or collagenase. Serum stimulation was assumed to induce the same response as growth factor stimulation, and therefore these individual gene products were assumed to regulate cell growth. When Iyer and colleagues, using cultured fibroblasts, set out to study the response to serum addition not of an individual gene but of some 9000 human genes in parallel, they observed unique and unexpected patterns.¹ Rather than being involved in cell growth, many of the genes that were turned on by serum were known to be involved in wound healing, that is, tissue remodeling and repair. Suddenly, the serum response element in the collagenase gene, for example, made sense, also in physiologic terms. Since then, hundreds of biologic processes have been studied with the aim of understanding the properties of systems or subsystems (i.e., smaller units with unique properties). In an era in which pathophysiologic variations between individual humans need to be interpreted on the basis of their genomic composition and epigenetic state, the systems perspective is the only existing route to translate molecular information into physiologic meaning and should therefore be important for all physicians.

KEY TECHNOLOGIES EMPOWERING SYSTEMS BIOLOGY

Traditional hypothesis-driven research is being bypassed by data- or systems-driven research for the unbiased exploration of the properties of a system that can then be used to generate novel hypotheses. Systems biology typically studies biologic systems by systematically perturbing them (biologically, genetically, or chemically), monitoring the gene, protein, metabolite, and informational pathway responses, integrating these data, and ultimately formulating mathematical models that describe the structure of the system and its response to individual perturbations (Fig. 17.2).² It is important to note for the medical reader that a genomic alteration from the norm, such as a mutant gene or a rare allele, in this context represents a perturbation of the system. Hood and Flores have described this systems approach as the virtuous cycle of “biology drives technology drives computation and mathematics.”³ Technology advancements lead to new data types that in turn require new computational and mathematical tools giving rise to a better understanding of the system in an iterative cycle.

Fig. 17.1 Systems biology is understanding the wiring of whole molecular pathways and organisms. Systems approaches include “-omics” technologies to make informed decisions regarding a healthy or pathologic process in a patient.

Fig. 17.2 In systems biology, networks of interacting molecules are placed between genotype and phenotype. Each node (depicted as a circle) represents either a gene, protein, or metabolite. Gene, protein, metabolite, and pathway responses are monitored following biologic, genetic, or chemical perturbation. Computational and mathematical tools eventually aid in better understanding the system. siRNA, small interfering RNA; TNF- α , tumor necrosis factor- α .

In Table 17.1 the key data-gathering techniques for generating quantitative and qualitative data for systems studies are described. For a more in-depth review of the concepts of systems biology and its impact on human biologic research, the authors highly recommend further reading in the *Handbook of Systems Biology*.⁴ A complete description of methods used to create computational models and conduct simulations of immune function is discussed in detail elsewhere.⁵ The “-omics” technologies such as those presented in Table 17.1 have the potential to transform medicine from traditional symptom-oriented diagnosis and treatment of diseases toward disease prevention and early diagnostics.⁶

Analysis tools and data management

Systems biology research projects often create data sets of enormous size and diversity. Biologic systems display complex behaviors that can seldom be interpreted in terms of linear relationships between the elements that compose them. Rather, these components are highly connected and in complex, nonlinear relationships with each other, such as feedback mechanisms and other regulatory loops and relays. Therefore bioinformatics and modeling skills have become essential elements in systems approaches. Large data sets can be sorted by applying statistics, algorithms, and software developed by mathematicians and computational scientists. The aim is to make testable predictions about the system, for example, how the overall system will be affected by alterations in the concentration of a component that influences the efficiency of a certain element. An important point is that the software solutions being developed must be driven by the needs of the systems biologists actually interested in understanding the human physiologic process. Furthermore, there is a need to make both data generation and data analysis tools accessible to all scientists to better catalyze worldwide scientific progress. This requires standardization efforts and widespread data sharing. In addition to rewarding researchers by offering publication-like citations (in the form of digital object identifiers, or DOIs) for voluntarily publishing data or by providing attractive data management systems supporting their work, the best way to promote a culture of data sharing is by making data management and sharing a condition for funding. Besides policies and incentives, development of appropriate data management systems is indispensable.

The basic requirements for a large-scale systems biology data management system are the following:

- Automated data collection approaches: providing data storage and data security
- Data integration: providing metadata and data standardization to make data comparable
- Data delivery: making data publicly available, thereby facilitating systems biology research

This is true for the clinical laboratory setting as well as for the basic large-scale biologic research laboratory. Further requirements are the extensibility to new data types and functionality as well as carefully designed interfaces for integration with other systems in a continuously changing environment. Support for modeling of data and uploading to public repositories, such as the National Center for Biotechnology Information Gene Expression Omnibus, European Bioinformatics Institute ArrayExpress, PeptideAtlas, or BioModels, are equally important. A comprehensive review and a more detailed discussion of data management systems successfully employed in large-scale systems biology projects is available elsewhere.¹²

Data standardization and integration

As mentioned earlier, two major challenges in systems biology are data standardization and integration. Data come in different formats, metrics, and degrees of statistical significance. Often data have been obtained using different systems, protocols, and/or reagents (e.g., cell type, species, growth conditions, biochemical handling). Biologic objects, be they genes, proteins, or tissues but also diseases, suffer from an international lack of standardized language and nomenclature. This is a fundamental impediment to data comparison and integration that is often dealt with by making compromises, which affect the reliability of observations.

Data standardization

A multitude of initiatives have been taken in recent years to assign non-equivocal nomenclature to biologic objects as well as to create computational modeling languages that can deal with nonuniform data sets. Data comparison and exchange are considerably easier within a technologic area (e.g., genomics) than between different areas (genomics vs. metabolomics). The Minimum Information for Biological and Biomedical Investigations recommendations represent the agreed international community standards in the field needed to reproduce experiments and are complemented by many other standards, such as the proteomics standards initiative—molecular interactions in the proteomics field, the mass spectrometry markup language in the mass spectrometry area, BioPax as the exchange format for pathway data, and the systems biology markup language for the description of systems biology models in xml.

Data integration

Data intersection and integration are nevertheless very powerful in unearthing patterns that would otherwise be difficult to discern. For example, the

TABLE 17.1

Three questions on the key technologies empowering systems biology

What is it?	How is it done?	What is it good for?
Genomics		
Comprehensive characterization of whole-genome sequences of individuals (patient groups, ethnic groups)	High-throughput parallel sequencing by next-generation sequencing (NGS) technologies	Determine correlation with disease through statistics, computational modeling (e.g., the International Cancer Genome Consortium efforts in cancer genomics) ⁷
Epigenomics		
Characterization of changes in chromatin states and gene regulation that can be inherited on top of the genomic DNA sequence	Determination of whole-genome DNA methylation profile by bisulfite sequencing, mapping of chromatin domains associated with particular modifications (histone acetylation, methylation, etc.), characterization of noncoding RNAs	Essential to explain the environmental context-dependent genotype-to-phenotype transition (as addressed, e.g., by the International Human Epigenome Consortium and the ENCODE [ENCyclopedia of DNA Elements] projects) ^{8,9}
Metagenomics		
Characterization of the genomic information present in particular samples (e.g., feces, hair follicles, saliva) to determine the composition of the human microbiota	Genomics technology followed by computational deconvolution, with avoidance of human sequencing by filtering	Represents critical interface between body and environment and can be also causally associated with human disease (e.g., inflammatory bowel disease) as reflected by the initiative of the Human Microbiome Project ¹⁰
Transcriptomics		
Characterization of genomes in action, mapping of all coding and noncoding RNAs in a given tissue under a given condition	NGS technologies of RNA converted to DNA by reverse transcriptases and if necessary amplified by polymerases; NGS enables whole transcriptome sequencing (RNA-seq) and provides a high resolution and more quantitative alternative to microarrays	Reveals "fingerprint" and gene expression program of particular state of cells and tissues
Proteomics		
Parallel characterization of proteins (presence thereof, their interactions, modifications)	Mass spectrometry (mostly), protein arrays, or indirect genetic tools (yeast two-hybrid methods)	Measures endpoints of gene expression and their properties; identifies targets and receptors of agents and characterizes biomarkers
Metabolomics		
Parallel profiling of selected groups of metabolites (lipids, sugars, amino acids, etc.)	Selective enrichment by biochemical means followed by mass spectrometry (mostly) or chromatography	Provides powerful measurements of gene activity integration within environmental context
Phenomics		
Integration of all quantifiable molecular and nonmolecular features of a biologic system, including aspects of cell, tissue, organism shape, and appearance	All of the technologies above as well as high-content small interfering RNA screening and computer-assisted imaging	Allows for integration of many features not currently standardized (e.g., cell shape) but reflective of molecular action (cytoskeletal proteins)
Systems pharmacology		
Characterization of single or combination pharmacologic agents (small molecules, drugs, and biologics) by ability to perturb biologic systems	Integration of the approaches above, medicinal chemistry, chemoinformatics, and computational tools	Used for prediction of adverse effects, second medical use, strategic use of combination therapy and polypharmacology
Systematic single-cell analysis		
Use of all technologies above at single-cell resolution	Computer-assisted multiparameter microscopy (confocal, other), mass cytometry (fluorescence and mass spectrometry detected), ¹¹ as well as chip and microfluidic technologies	Avoids confounding averaging of molecular parameters over heterogeneous populations; allows detection of stochastic processes
Network analysis		
Organization of components of biologic systems in networks of physical interaction or other measurable relationships (clustering of properties, temporal order of expression of genes, etc.)	Graph theory and topologic analysis borrowed from mathematics	Detects functional relationships among molecules or among properties, predicts function of network members and regulatory properties of subnetworks
Computational modeling		
Use of computer and mathematics to imitate and predict the behavior of biologic systems	Algebraic or probabilistic mathematical tools, differential equations, flow analysis to obtain quantitative and dynamic biologic models	Allows one to test depth of mechanistic understanding of a process and ultimately to obtain tools predictive of diagnostic reliability or therapeutic outcome

combination of data on gene expression at the messenger RNA (mRNA) level (resulting from, e.g., quantitative sequencing of the ensemble of mRNAs in cells) and the protein level (resulting from, e.g., quantitative proteomic analysis) can synergize in conferring significance to observed changes. The ability to additionally obtain corroborating evidence by using

corresponding changes in metabolite composition or drug sensitivity, or by using a different cellular system, enhances the importance of the observed changes dramatically. Simple computational algorithms are used to parse or screen for synonyms and infer data from other species using gene orthology, whereas probabilistic statistical models are often used to deal with

incomplete data sets. There are advantages to keeping different experimental models (e.g., different cell lines or animal models) despite the trends toward standardization. It is critical, however, to maintain a high degree of normalization and controlled, defined language, particularly in medicine when sampling and processing patient tissues for analysis, to unleash the true potential of approaches at the systems level.

Models and networks

Essential to the discovery cycle of systems biology is the ability to derive and test models that should mimic physiologic events, such as the prediction of a molecular pathway to convey a signal or turn over a metabolite.¹³ For this, data that can be computed are a prerequisite, thus quantitative biology must go hand in hand with systems biology. This dovetails in a more medical sense with accurate parameters from laboratory medicine and genomic medicine. Two types of data can be distinguished. One is numerical and represents the quantity of a particular property, such as the affinity of one protein for another, the turnover rate of an enzyme, or the concentration of a metabolite or an mRNA. The other is topologic and represents the relationship of one biologic entity to another, such as the position in a greater network—for example, being “upstream” or “downstream” in a process. Additionally, the dimensions of time and space, as both numerical and topologic parameters, may vary. The ability to model actual physiologic situations necessitates gathering knowledge about both the “hierarchy” of a process and the architecture of the possible information flow associated with it, as well as values that quantify the individual components. Thus most systems biology models are based on molecular networks. When the networks are large, such as gene-regulatory networks and protein-protein interaction networks, useful information can be inferred from the structure of the network; for example, whether particular nodes (in network language, objects are “nodes” and connections or relationships are “edges”) represent bottlenecks, or how central they are in the process. This may indicate that particular genes, for instance, are master regulators. In the case of protein-protein interactions, preferred protein partners may always be found together, and together combine with alternate additional partners, which suggests modularity in the organization of proteomes. When the system under investigation is characterized well enough in terms of quantitative parameters such as enzyme kinetics, it has been useful to model its ability to process biologic matter or information. The intermediate metabolism of entire organisms, the sequence of events in cell cycle regulation, and even the oscillatory pattern of certain transcriptional processes have all been modeled successfully. Large research consortia are now tackling orders of magnitude more complex processes, such as the functions of a human liver.¹⁴

CASE STUDIES

Four selected global analyses are described in detail in the following sections as a first step toward a systems-level view of the complexity of biologic processes.

Host factors regulating infection across mammalian viruses

High-content small interfering RNA (siRNA) screens have been successful in systematically identifying new disease genes and in gaining insights into signaling networks. Currently, the two largest technical problems with this technology are the inconsistencies between the phenotypes generated by different siRNAs targeting the same gene, and weak comparability of similar siRNA screens performed by different laboratories or in different cell lines or using different siRNA libraries. A striking example is the largely nonoverlapping hit list (less than 7% overlap) produced in three published screens that identify host factors required for human immunodeficiency virus infection.¹⁵ Applying single-cell and computational analysis, Lucas Pelkmans and colleagues could significantly improve the reproducibility of siRNA screens when the population heterogeneity of cell lines was considered.¹⁶ More than 40 siRNA screens analyzing 17 different mammalian virus infections and related physiologic processes such as lipid homeostasis, endocytosis, and cell size regulation in two different cell lines were performed in this complex study. Measuring virus uptake as well as 200 cellular features at the single-cell level improved the reproducibility of hit lists of host factors required for the uptake of the same virus across different cell lines and between siRNAs required for the uptake of different viruses in the same cell line. With these hit lists, systems-level insights into host signaling networks involved in viral infection could be gained. Two distinct envelope-dependent

strategies by which viruses hijack regulation of protein translation can be deduced from this study. For example, of the 49 human kinases tested that have previously been shown to play a role in virus infection and endocytosis, DYRK3 and FRAP1 (also known as *mTOR*) had the most global effects on virus infection. More than half of all enveloped virus infections were more sensitive to DYRK3 silencing than to FRAP1 silencing, whereas most of the nonenveloped virus infections were more sensitive to FRAP1 silencing. Interestingly, FRAP1 is known to regulate protein translation, and the yeast homologues of FRAP1 and DYRK3 are known to play opposite roles in protein translation, which suggests that virus particle structure and type constrain the host cellular mechanisms that can be hijacked for infection.

Model of a mammalian transcriptional network mediating the differential response to pathogens

Amit and colleagues¹⁷ developed one of the first transcriptional networks for the mammalian innate immune system. As a case study they used the innate immune response of dendritic cells through Toll-like receptors. First, RNA microarrays were applied as a global profiling technology to measure the component states. Primary mouse dendritic cells were stimulated with Toll-like receptor ligands and genomewide mRNA levels were profiled over time. Second, a provisional network model was devised based on the coexpression of transcription factors and their putative targets. This included the nomination of 144 candidate regulators and the identification of 120 reporter or signature genes for monitoring the effects of perturbing regulators. In a third step, predictions of the resulting model were experimentally tested using a genetic network perturbation approach. Lentiviral small hairpin RNAs were used to silence the expression of the selected candidate transcriptional regulators, and a multiplex mRNA detection system was used to quantify the effect of each gene knockdown on the expression of the chosen signature genes. This allowed the construction of a network model that linked candidate regulators with specific target genes. The core network consists of 24 regulators encompassing both the inflammatory response (enriched for nuclear factor- κ B [NF- κ B] and other inflammation-responsive genes) and the antiviral response (enriched for interferon response factors and viral and other interferon-responsive genes). In the inflammatory response, several feed-forward loops were identified that may ensure response only to persistent and not to sporadic signals. In the antiviral response, a two-tiered circuit was discovered involving feedback and feed-forward loops, implicating a new module of cell cycle regulators not previously associated with this response. Further, over 75 additional genes were identified to fine-tune the regulation of target genes. From a biomedical perspective, identification of entire regulatory arms (viral vs. inflammatory) allows therapeutic targeting of specific pathways to control disease or enhance vaccine efficacy. To gain an even deeper understanding of the specific network components, this approach can be complemented by using proteomics and phosphoproteomics to select and test additional candidate regulators with mRNA levels that are unchanged in the immune response under study.

Topologic insight into the tumor necrosis factor- α /nuclear factor- κ B subnetwork

Affinity purification (AP) of proteins and identification of co-purified interactors by mass spectrometry (AP-MS) has become the preferred method for the analysis of protein-protein interaction networks because it produces data that better reflect the physiology of the system and the multidirectional complexity of a network. A systems approach was applied using AP-MS to map a protein-protein interaction network around 32 known and candidate tumor necrosis factor- α (TNF- α)/NF- κ B pathway components, and functional RNA interference (RNAi) perturbation assays to identify key modulators of the pathway.¹⁸ More than 200 molecular interactions were identified, about 70% of which were already known. A further 80 proteins not previously implicated in NF- κ B signaling were also identified, including 10 modulators of the pathway as shown by the combined loss-of-function analysis. Combining RNAi perturbations with AP-MS to map the physical and functional interactions of human signaling pathways is a paradigm for future studies, providing plenty of data to be followed up by more directed investigations. Another pathway relevant to human disease elucidated by AP-MS and RNAi is the autophagy pathway.¹⁹

Mathematical model for tumor necrosis factor- α -induced nuclear factor- κ B signaling

Whereas the previous example provides a wealth of topologic data about a signaling pathway relevant to human disease, this example contributes

quantitative data to this pathway. NF- κ B dynamics were measured in high throughput with a microfluidic cell culture system and live-cell imaging. The response of thousands of single cells was measured for a wide range of TNF- α concentrations. NF- κ B-dependent gene expression was also measured, and a model was presented to explain these findings.²⁰ In contrast to population studies, NF- κ B activation was shown to be heterogeneous at the single-cell level and is a digital process with fewer cells responding at lower TNF- α doses. Cells also encode a set of analogue parameters to modulate the signaling outcome, such as the timing, intensity, and number of transcription factor oscillations, to create digital outputs, such as activation and early gene expression. Early gene expression is not dependent on the inducing signal intensity, whereas the expression of later genes requires persistent nuclear localization of NF- κ B, which exists only at the highest input signal levels. Elucidation of NF- κ B activation as a case study in systems biology has been very productive, leading to the study of NF- κ B dynamics in response to different TNF- α concentrations and time-varying TNF- α stimulation, as well as with different ligands, on drug perturbations, and in response to bacteria. The example described here represents one of several model-driven studies performed in the last 10 years.

FUTURE OF SYSTEMS BIOLOGY IN RHEUMATOLOGY

A surge of systems-level studies of inflammatory processes can be envisaged. Over the next 3 to 5 years, genomic sequences will likely be available for all patients seeking treatment for serious inflammatory conditions. There will be the potential for patients to increasingly sample both data on their own health state and information from Internet resources. Yet what will be critical is the ability to interpret the somatic epigenetic changes associated with the diseased state in the diseased tissue in the context of particular environments (e.g., microbial, dietary, smoking). Possibly this will be inferable from data obtained using serum samples or directly from biopsy

specimens. Computer models based on the molecular networks of the inflammatory process and on the mechanism of action of the available therapeutics will triangulate data on therapeutic outcome from large databases and suggest patient- or group-specific treatments. The following are areas of activity in which particular progress can soon be expected:

- Creation of comprehensive diagnostic and prognostic profiles of cytokines, chemokines, and other secreted factors based on systems-level evaluations (away from individual levels and combinations) through application of the recently developed mass cytometry approach
- Appreciation of differences between large groups of responders compared with nonresponders to signaling network responses to antiinflammatory single and combination therapies
- Single-cell-resolution mapping of differential healthy and nonhealthy expression profiles of most cell types involved in inflammation (including new cell types soon to be discovered by molecular profiling)
- Exhaustive characterization of human proteins of the innate immune system devoted to antimicrobial detection and their potential role in autoimmunity
- Comprehensive characterization of the human body-associated microbiome (intestine, oral cavity, skin) and its association with inflammatory conditions

ACKNOWLEDGMENTS

The authors wish to thank their colleagues for discussion and feedback, their families for tolerance, and the following individuals for critical review of the chapter: Helen Pickersgill, Andreas Bergthaler, Christoph Bock, Stefan Blüml, and Thomas Karonitsch. Research in the Superti-Furga laboratory is supported mainly by the Austrian Academy of Sciences and the i-FIVE ERC grant.

Epigenetics in rheumatology

■ CAROLINE OSPELT ■ STEFFEN GAY

- Epigenetic modifications consist of DNA methylation and modifications of histone tails.
- Epigenetic modifications can be changed by environmental influences and can be restored after mitosis and meiosis.
- Epigenetic modifications of chromatin render it more or less accessible for transcription factors and thereby define which genes in a cell are transcribed.
- Even though DNA methylation always leads to gene silencing, histone modifications can enhance or suppress gene transcription, depending on the modification.
- Global DNA hypomethylation and hypomethylation/hypermethylation at specific promoters occur in immune and stromal cells in rheumatic diseases.
- Changes in histone acetylation, methylation, and SUMOylation have been found in rheumatic diseases.
- MicroRNA is small inhibitory RNA whose expression is regulated by epigenetics and which in turn regulate the expression of epigenetic enzymes.

WHAT IS EPIGENETICS?

Expression of genes in a cell is regulated on three different levels. First, the genetic code determines which proteins can potentially be made by an organism. Second, the epigenetic code modifies chromatin so that it is accessible for transcription or not. Third, transcription factors bind and initiate the transcription of a gene.

All proteins made by a cell are encoded in the genetic code. The sequence of the DNA determines the genotype, which is unique for each individual. However, even though each cell of the body contains the full and identical genetic code, different proteins are made by different cells according to their functions. This specific pattern of transcribed genes is the basis for the different phenotypes of the cells in the body and is maintained by the epigenome. Epigenetic modifications of chromatin render it more or less accessible to transcription factors and thereby define which genes in a cell are transcribed.

To ensure that each daughter cell has the same gene expression pattern as its predecessor and can thus fulfill the same function, the epigenetic code, just as the genetic code, must be heritable. In contrast to the genetic code, however, the epigenetic code must also be modifiable so that the changes in gene expression needed during development and differentiation can occur. Heritable epigenetic modifications are restored after mitosis and also after meiosis and thus are passed not only to daughter cells but also to following generations. Transient epigenetic changes are placed and removed, depending on the current requirements of the cell. Accordingly, changes in the epigenetic code can be introduced by environmental conditions. By these means the cell can adapt to changes in its environment by stable alterations in its gene expression pattern.

An impressive example of the interaction of the environment with the epigenome is maturation of the queen bee in a bee hive. The contents of the royal jelly are able to influence epigenetic modifications such that only the larva that is fed royal jelly can express the genes necessary to grow into the queen bee.¹ Similarly, nutrition can also influence the epigenetic code in mammals. Key experiments by Waterman and colleagues showed

that feeding pregnant agouti mice a special diet of folic acid and vitamin B₁₂ changes the fur color of their offspring.² These remarkable phenotypic changes are induced by epigenetic silencing of the agouti gene. In addition, environmental influences can introduce epigenetic changes in humans that are still visible in the offspring. For example, epigenetic modifications that silence expression of the insulin-like growth factor II gene have been found in children whose mothers were pregnant during the Dutch Hunger Winter of 1944/1945.³

Already in 1957 a strong influence of the environment on the epigenome and thus on cellular differentiation and function was propagated by Conrad Waddington.⁴ However, only in recent years has epigenetic research been widely acknowledged. The more the field advances, the more diseases are found in which the epigenome is affected and possibly contributes to the development and persistence of disease. In parallel, drugs that modify the epigenome are developed in the hope that pathologically changed gene expression can thus be permanently corrected.

THE BASIC MECHANISMS

Epigenetic modifications are placed directly at the DNA base cytosine or at the protruding tails of the histones. They can directly and indirectly affect gene transcription. Direct effects are induced by changes in the packing of chromatin and thus alter its accessibility for transcription factors; indirect effects are mediated by the recruitment of effector molecules.⁵

Histone modifications

The five histone proteins H1, H2A, H2B, H3, and H4 keep the DNA packed within the nucleus so that the positively charged amino acids of the histone tails interact with the negatively charged phosphate backbone of the DNA. If negatively charged epigenetic modifications are placed at the histone tails, they induce a conformational change that loosens the chromatin structure and thus induces the formation of transcribed euchromatin. Other modifications tighten the packaging of the DNA, which results in inactive heterochromatin. In addition, effector molecules are bound that lead to stabilization or inhibition of the transcription machinery.⁵

A variety of different modifications of histone tails are known, namely, acetylation, methylation, phosphorylation, ubiquitination, SUMOylation, and adenosine diphosphate (ADP) ribosylation. These modifications are not isolated but are interconnected and influence gene transcription in combination or sequentially. Even though all these histone modifications are assumed to modulate transcriptional activity, they vary greatly in their stability and impact. Up to now, however, no direct evidence has shown that these histone modifications themselves initiate changes in gene expression. Instead of being activating or repressing by themselves, histone modifications might also be installed at active or silent chromatin to stabilize the current status.⁶ Nevertheless, certain acetylation and methylation marks strongly correlate with euchromatin and heterochromatin, respectively.⁷ Other modifications, however, could not so clearly be connected to a transcriptional activity state.

Histone acetylation

Histone acetylation is a rather transient histone modification that is not heritable. Histones are acetylated by histone acetyltransferases (HATs) and deacetylated by histone deacetylases (HDACs). HATs and HDACs are promiscuous enzymes that in addition to acetylation of histones, also catalyze the acetylation of transcription factors, oncoproteins, and tumor suppressors.⁸ HDACs have come into focus in recent years because of the development of HDAC inhibitors and their successful application in cancer therapy. The HDAC family consists of 18 members that are classified into 4 groups.

The HDACs in group III, the sirtuins, are nicotinamide adenine dinucleotide dependent, whereas the rest of the family is zinc dependent. The commonly used HDAC inhibitors work by blocking the Zn activity site and accordingly inhibit the function of all class I, II, and IV HDACs, but not the Zn-independent sirtuins. How much the therapeutic action of HDAC inhibitors stems from the resulting increase in histone acetylation or acetylation of nonhistone proteins has not been clarified to this point.

Histone tails are acetylated at lysines. Acetylated lysines are found in histone tails at sites of actively transcribed DNA. Acetylation neutralizes the positive charge of the histone tails and thus decondenses the chromatin.^{9,10} Proteins with a bromodomain can recognize acetylated histone tails and bind to them.¹¹ The bromodomain is commonly found in proteins that are known to remodel chromatin and regulate transcription. Thus, acetyl residues placed at lysines in the histone tails support gene transcription by conformational changes in chromatin and by attraction of activating effector proteins.

Histone methylation

Histone methylation is much more stable than histone acetylation and is preserved during cell division. It plays a crucial role in embryogenesis and initiates silencing of the inactive X chromosome in female cells.¹² Methyl residues are placed mainly at arginines or lysines of the histone tails by histone methyltransferases (HMTs). Methylation of histidines has also been described, but its function is largely unknown.¹³ Depending on the HMT, arginines are monomethylated or dimethylated, whereas lysines are monomethylated, dimethylated, or trimethylated.¹⁴ Even though methylation at lysines can be removed by demethylases, no enzyme that directly removes methyl residues from arginines has been found thus far. However, monomethylated arginine can be deaminated to citrulline by peptidylarginine deiminase 4 (PAD4). Citrullination is associated with transcriptional repression.¹⁵ Demethylation of methylated lysine is catalyzed by proteins that contain an amine oxidase or a Jumonji C (JmjC) domain.

Methylation can enhance as well as repress transcription. The effect on gene transcription depends on the location and quantity of methyl residues placed at the amino acids. For example, three-methyl residues (trimethylation) at lysine number 4 of the tail of histone 3 (H3K4me3) are found at sites of active gene transcription, whereas trimethylation of lysine number 27 (H3K27me3) suppresses gene transcription.^{16,17} Importantly, a combination of different methyl marks, as well as a combination of methyl marks with other histone modifications, can largely influence the outcome. The effect of these combinatorial histone modifications on gene transcription is mediated by the binding of different effector complexes. Additionally, these effector complexes can lead to further modifications (e.g., deacetylation if they have HDAC activity), which reinforces the effect of a methyl mark.¹⁸

Methyl marks on histones are bound by proteins with methyl-binding properties like plant homeodomain (PHD) fingers and by the Royal superfamily of chromatin-binding proteins containing, among others, chromodomain, Tudor domain, and malignant brain tumor (MBT) domain.^{5,19,20} The proteins that recognize methyl marks can either directly activate or repress transcription or can recruit chromatin-remodeling complexes.^{19,21}

Histone methylation has also been suggested to induce chromosomal looping, which brings gene elements such as promoters in close contact with genes of a different genomic region.²²

Phosphorylation

Phosphorylation is a histone modification that is induced rapidly (e.g., after stress stimuli) but is equally removed rapidly.²³ A longer-lasting effect of histone phosphorylation is, however, achieved by interconnection with other, more stable histone modifications. Phosphorylation can, for example, entail histone acetylation and methylation.^{24,25} In particular, phosphorylation and acetylation work in synergy since both of them negatively charge histones and thereby loosen their connection to the DNA. Furthermore, phosphoacetylated histones are bound by 14-3-3 proteins, which initiate transcription. Phosphate groups on histone tails are also recognized by proteins with BRCA1 C-terminal (BRCT) domains.⁵

As other proteins, histones are phosphorylated by histone kinases at their serines and threonines and are dephosphorylated by phosphatases.

SUMOylation

Addition of the small ubiquitin-related modifier (SUMO) to lysines in the histone tail is called SUMOylation. SUMOylation is considered a counter player to acetylation since it occurs preferably at acetylated lysines and, by attracting HDACs, leads to removal of acetylation and repression of gene transcription.²⁶ Transcriptional repression can then be further reinforced by binding of heterochromatin protein 1 (HP1). HP1 works together with HMTs to induce stable repression via histone methylation.²⁷

SUMO is conjugated to lysines by E1 SUMO-activating enzymes, E2 SUMO-conjugating enzymes, and E3 SUMO ligases and removed by isopeptidases.²⁸

Ubiquitination

Even though SUMO and ubiquitin share structural features and both are conjugated to lysines, their function in transcriptional control is different. In particular at H2A, monoubiquitination is found at sites of active transcription, whereas in H2B it is associated with transcriptional repression.^{29,30} H3 and H4 have been shown to carry polyubiquitin marks, but their effect on gene transcription is not known yet.³¹ Ubiquitination exerts its effect by induction of other histone modifications, for instance, methylation and the formation of effector complexes that promote or inhibit transcription.³² Recent reports also suggest loosening of chromatin packaging as a result of the concerted action of ubiquitin and acetyl residues.³³

Ubiquitin ligases mediate monoubiquitination and polyubiquitination of histone lysines, which can be again deubiquitinated by deubiquitinating enzymes.

Adenosine diphosphate ribosylation

ADP ribosylation is probably the least studied histone modification. Although glutamic acid was described primarily as an acceptor site for ADP ribose in histones, it was later shown that histones are ADP-ribosylated at lysines.³⁴

Histones are mono-ADP-ribosylated by mono-ADP ribosyltransferases (MARTs) or poly-ADP-ribosylated by poly-ADP ribosyltransferases (PARPs).²⁴ Similar to histone ubiquitination, cooperation of ADP ribosylation with acetylation is assumed.³⁵

DNA methylation

The most common and best studied epigenetic modification of DNA is methylation of the cytosine ring resulting in 5-methylcytosine. Recently also, 5-hydroxymethylcytosine has been found in DNA.³⁶ The functional role of this modification, however, still has to be clarified. Since up to now no enzyme has been found that demethylates DNA, even though active DNA demethylation takes place in the genome, it has been proposed that the formation of hydroxymethylcytosine is an intermediate of the demethylating process.^{37,38} During development, DNA is globally demethylated in the paternal and at a later time also in the maternal pronucleus. In addition, changes in the methylation pattern occur in the fully developed organism, for instance, at the promoter of estrogen-responsive genes.^{39,40} Demethylation can occur either actively by removal of methyl marks or passively by lack of restoration of methylation marks after cell division.

Nevertheless, DNA methylation is the most stable epigenetic modification and is typically restored after mitosis and also meiosis. Although de novo methylation is accomplished by DNA methyltransferase 3a (DNMT3a) and DNMT3b, restoration of methyl marks after mitosis is catalyzed by DNMT1. Usually, these enzymes catalyze the addition of methyl marks to the cytosine ring at genomic locations with a high content of cytosine-phosphatidylguanine (CpG) dinucleotides, so-called CpG islands. In addition, regions that border CpG islands, which are called CpG shores, are methylated. This methylation pattern occurs mostly at sites of tissue-specific methylation.⁴¹

Apart from CpG methylation, DNA can also be methylated in a CHG or CHH context, where H can stand for adenine, cytosine, or thymidine.⁴² CHG or CHH methylation is found in pluripotent stem cells and disappears during cellular differentiation.

DNA methylation always represses gene transcription. Gene silencing by DNA methylation works by interference with transcription factor-binding sites or by recruitment of transcriptional repressors. Repressor proteins can also bind histone-modifying enzymes such as HDACs and thus lead to changes in the histone code.

DNA methylation is absolutely necessary for the repression of repetitive sequences such as *Alu* sequences and retrotransposons, genomic imprinting, X chromosome inactivation in female mammals, and tissue-specific gene expression. Accordingly, disturbances in DNA methylation have profound consequences on cell physiology.

A summary of epigenetic marks is provided in Figure 18.1.

EPIGENETICS IN DISEASE

Along with knowledge of the epigenetic mechanisms in healthy cells, more knowledge about epigenetic changes in disease has been gained. There are diseases in which alterations in the epigenetic machinery were found to be

Fig. 18.1 Epigenetics in the regulation of gene expression. AAA, poly A tail; Ac, acetylation; ADP, ADP ribosylation; Me, methylation; P, phosphorylation; SUMO, SUMOylation; Ub, ubiquitination.

Fig. 18.2 Events that can cause changes in the epigenome. DNMT1, DNA methyltransferase 1.

causative, in most diseases, however, changes in the epigenome were found to be associated with just the disease state, but it is not yet clear whether these changes are a cause or a consequence of the disease.⁴³

As mentioned earlier, epigenetic silencing of genomic regions is crucial for the proper formation of heterochromatin. In some cases, correct silencing of maternal or paternal parts of the genome is needed for a balanced expression of gene products. This is true not only for the X chromosome in female organisms but also for a variety of specific genes called imprinted genes.⁴⁴ In contrast to the normal diploid expression of genes, imprinted genes are haploid-expressed, which leads to a physiologic reduction in gene dosage. Currently, approximately 80 of these genes have been described in which physiologically only the maternal or the paternal allele is transcribed, but not both. On chromosome 15q11-13, for instance, certain genes are known to always be transcribed from the maternal chromosome and others only from the paternal. Disturbances in imprinting at this location, which leads to incorrect silencing or expression of the imprinted genes, are known to be one cause of Angelman syndrome and Prader-Willi syndrome.^{45,46} Similarly, disturbance in the imprinting process is one cause of the increased risk for tumor in patients with Beckwith-Wiedemann syndrome. In these patients, either the *H19* gene is totally silenced by hypermethylation of both alleles or methylation is lost at the IFG-II locus, which leads to diploid expression of this gene.^{47,48} In fragile X syndrome a CGG stretch in the 5' untranslated region of the fragile X mental retardation 1 (*FMR1*) gene is transformed into a CpG island by repeated duplication. By methylation of this newly formed CpG island the *FMR1* gene is silenced during development, which leads to mental retardation.⁴⁹

The early detection of epigenetic changes in some tumors suggests that epigenetic alterations can be causative in cancer.^{50,51} The genome of transformed cells is generally hypomethylated.⁵² In particular, loss of methylation at repetitive sequences leads to genomic instability (e.g., via gene disruption and genomic deletion).⁵³ Additionally, pathologic hypomethylation or hypermethylation occurs at gene promoters. As described earlier for Beckwith-Wiedemann syndrome, silencing of tumor suppressor genes or activation of oncogenes can confer a critical growth advantage to tumor cells. Changes in DNA methylation give rise to changes in histone modifications by recruitment of the respective enzymes. Accordingly, changes in histone acetylation and methylation are induced in many cancers.⁵⁴⁻⁵⁶

Changes in DNA methylation and histone modifications have also been found in neurodegenerative and neurologic diseases and in autoimmune and chronic inflammatory diseases.⁵⁷⁻⁶⁰ However, thus far it is mostly not clear

how and when altered epigenetic marks contribute to the pathogenesis of these diseases.

The origin of epigenetic alterations

Given that the epigenome can be modulated by the environment, it is tempting to assume that environmental risk factors induce epigenetic changes that lead to disease. Studies of monozygotic twins indeed show that the epigenome of these genetically identical individuals differs more and more over time.⁶¹ Different environmental influences could be the reason for this divergence. Increasing evidence, for instance, has shown that lipoproteins can influence the epigenome, which might be the first step toward the development of cardiovascular disease.⁶²

Another reason for changes in the epigenome over time might be failure of proper restoration of epigenetic marks after cell division. DNMT1, for instance, is not as accurate as DNA polymerase, which means that especially in highly proliferating tissues, mistakes in the restoration of methyl marks can accumulate.⁶³ Also, increased consumption of metabolites during fast proliferation can influence DNA methylation. The production of polyamines, for example, is increased in response to cellular stress, and accordingly, polyamine synthesis and, more importantly, recycling are activated in chronic inflammatory diseases.^{64,65} Polyamine recycling and DNA methylation, however, are both dependent on *S*-adenosylmethionine (SAM) as a donor for methyl groups. If the demand for polyamines is high, SAM is used mainly for polyamine recycling, thus leaving too little SAM for proper DNA methylation.

Another important point regarding the role of epigenetics in disease development is its fundamental role in embryogenesis and cell differentiation. Limitations of the epigenetic machinery early in life could lead to pathologic conditions at a later time. Studies examining patients who were exposed to prenatal malnutrition suggest that such disturbances in development of the central nervous system lead to mental illness.^{66,67} The mechanisms that can lead to epigenetic changes are summarized in Figure 18.2.

Rheumatic diseases and epigenetic changes

Several aspects of rheumatic diseases make this field interesting for epigenetic research. The risk for development of a rheumatic disease is increased with age, smoking is an environmental risk factor for most of the rheumatic diseases, and the inflammatory process leads to an increase in cellular stress,

which can be an initiator of epigenetic changes, as mentioned previously. Furthermore, concordance rates for rheumatic diseases in monozygotic twins are often low, thus pointing to nongenetic factors influencing the incidence of these diseases. Changes in DNA methylation and histone modifications have been found in the immune and stromal cells of patients with rheumatic diseases. They might be the basis for dysfunctions of the immune system, as well as for the chronicity of rheumatic diseases.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is currently the most studied rheumatic disease with respect to epigenetic changes. In SLE, heritability explains around two thirds of cases.⁶⁸ Interestingly, DNA methylation differs significantly between monozygotic twins when one twin is healthy and the other has SLE.⁶⁹ DNA hypomethylation is found in SLE T cells, which was speculated to be caused by a defective ras mitogen-activated protein kinase (MAPK) signaling pathway leading to diminished levels of DNMT1.^{70,71} Several studies have convincingly shown that on hypomethylation, T cells change their gene expression pattern and become autoreactive.^{72,73} In particular, hypomethylation induces the expression of CD70 and CD11b in lupus T cells, which has been implicated in the initiation of autoreactivity.⁷⁴⁻⁷⁶ Also, expression of perforin is induced by hypomethylation in the T cells of lupus patients.⁷⁷ Perforin promotes macrophage cell death, which in conjunction with the disturbed clearing of cell debris in SLE, was proposed to promote the formation of autoantibodies against DNA. In vitro, demethylation induces the expression of human endogenous retrovirus (HERV) sequences in peripheral blood cells.⁷⁸ Since in vivo peripheral blood cells from patients with SLE aberrantly express HERV, it has also been assumed that the loss of silencing of these repetitive sequence is due to hypomethylation.⁷⁹ Expression of HERV has been suspected to induce autoimmune reactions either by altering gene expression or by acting as superantigens.⁸⁰ Accordingly, expression of HERV transcripts correlates with the presence of the antinuclear antibodies anti-U1 ribonucleoprotein and anti-Sm.⁸¹ A strong argument for a causative role of hypomethylation of T cells in the subsequent changes in gene expression comes from mouse models, where transfer of in vitro hypomethylated T cells leads to an autoimmune response similar to that seen in human patients with SLE.⁸²

Regarding histone modifications, the histones H3 and H4 in lupus T cells have been found to be globally hypoacetylated but hyperacetylated at specific sites (e.g., the CD70 locus).^{83,84} At the CD70 promoter an increase in the active H3K4me2 mark was also found.⁸⁴ A genome-wide study discovered significant changes in the active H4K4me3 mark when comparing blood

cells from SLE patients with those from healthy individuals and patients with rheumatoid arthritis (RA).⁸⁵

Rheumatoid arthritis

In RA, studies of monozygotic twins have shown that only about two thirds of cases of disease can be explained by genetics.⁸⁶ This is significantly lower than, for instance, in celiac disease, where the concordance rate for monozygotic twins is higher than 80%.^{87,88} Epigenetic changes that arise over time or in response to environmental influences might explain why RA develops in one twin whereas the other stays healthy. In patients, changes in the epigenome are found in peripheral blood cells, as well as in resident cells of the joints (i.e., synovial fibroblasts). Most studies have looked at DNA methylation, whereas studies investigating histone modifications in RA are still rare.

Global demethylation was found in T cells and in particular in CD4+CD28- cells of RA patients.^{70,89} In patients with chronic inflammatory diseases, as well as in the elderly, expansion of CD4+ T cells that lack CD28 expression is commonly seen.^{90,91} Along with the loss of CD28, these cells are also characterized by a different functional profile. The specific gene expression pattern seen in these cells can partly be explained by decreased levels of DNMTs and consequent loss of methylation at specific gene promoters.^{89,92} Apparently, continuous proliferative stress inhibits extracellular signal-regulated kinase (ERK) and Jun N-terminal kinase (JNK) signaling, which in turn downregulates the expression of DNMTs.⁹² Other studies analyzing peripheral blood cells found loss of methylation at the promoters of interleukin-6 and ephrinB1 to be a cause of the increased expression of these genes in patients with RA.^{93,94}

In parallel to the hypomethylated state in peripheral blood cells, synovial fibroblasts of RA patients were found to be globally hypomethylated.⁹⁵ Also, the lack of DNMT1 during proliferation in this case is assumed to cause improper restoration of methyl marks after cell division.⁹⁵ Additionally, an increase in polyamine recycling could be shown in RA synovial fibroblasts, which as mentioned earlier can aggravate DNA demethylation.⁹⁶ Loss of methylation in RA synovial fibroblasts leads to the expression of LINE-1 retrotransposons, as well as to increased levels of CXCL12.^{97,98} Similar to what is found in cancer cells, in RA synovial fibroblasts, hypomethylated and hypermethylated genomic sites are also found.⁹⁹ For instance, death domain receptor 3 (DR-3) expression is low in RA synovial fibroblasts because of hypermethylation.¹⁰⁰

Data describing histone modifications in patients with RA are scarce. HDAC activity was found to be higher in peripheral blood cells and HDAC1

TABLE 18.1 Overview of epigenetic changes in rheumatic diseases

Disease	Cell type	Modification	Affected genes	Consequences	References
SLE	CD4+ T cells	DNA hypomethylation	Global, CD70, CD11a, perforin, HERV (?)	Increased expression, autoreactivity, macrophage death, autoantibody formation (?)	70, 74, 75, 77, 79
	CD4+ T cells	Histone H3 and H4 deacetylation	Global		83
	CD4+ T cells	H3 hyperacetylation	CD70	Increased expression	84
	CD4+ T cells	Increase in H3K4me2	CD70	Increased expression	84
	PBMCs	Increase in H3K4me3	Global		85
RA	CD4+ T cells	DNA hypomethylation	Global		70
	CD4+CD28- T cells	DNA hypomethylation	Global		89
	PBMCs	DNA hypomethylation	IL-6, ephrinB1	Increased expression	93, 94
	Synovial fibroblasts	DNA hypomethylation	Global, LINE-1, CXCL12	Increased expression	95, 97, 98
	Synovial fibroblasts	DNA hypermethylation	DR-3	Decreased expression	100
	PBMCs	Increased HDAC activity	Global		101
	Synovial fibroblasts	Increased HDAC1	Global		102
	Synovial tissue	Increased /decreased HDAC activity	Global		103, 104
Scleroderma	CD4+ T cells	DNA hypomethylation	Global		110
	Skin fibroblasts	DNA hypermethylation, histone deacetylation	FLI1	Decreased expression, increased collagen synthesis	111
ANCA vasculitis	Neutrophils	Loss of H3K27me3	Proteinase 3, myeloperoxidase	Increased expression, autoantibody formation (?)	112
Osteoarthritis	Chondrocytes	DNA hypomethylation	MMP-3, MMP-9, MMP-14, ADAMTS4	Increased expression	113
	Chondrocytes	Increased HDAC7	Global	Increased MMP-13	114

ANCA, antineutrophilic cytoplasmic antibody; HDAC, histone deacetylase; HERV, human endogenous retrovirus; IL-6, interleukin-6; MMP, matrix metalloproteinase; PBMCs, peripheral blood mononuclear cells; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

expression higher in synovial fibroblasts of RA patients.^{101,102} Findings on the activity of HDACs in RA synovial tissues are inconsistent; such activity was described to be higher as well as lower than in osteoarthritis synovial tissues.^{103,104} Since acetylation is a rather transient histone modification that responds rapidly to environmental changes, such as levels of tumor necrosis factor, selection of patients could be a decisive bias in this type of studies. It is notable, however, that pan-inhibitors of HDACs have a beneficial effect in various arthritis animal models, and trials in humans are eagerly awaited.¹⁰⁵⁻¹⁰⁸ Also, SUMOylation seems to be affected in RA synovial fibroblasts, which in connection with HDAC4 changes the expression of matrix metalloproteinase 1 (MMP-1).¹⁰⁹

Other rheumatic diseases

Even though epigenetic studies are much more advanced in SLE and RA, changes in the epigenetic machinery have also been found in other rheumatic diseases. An overview of the findings is provided in Table 18.1. In general, it can be said that global DNA hypomethylation evolves in peripheral blood and stromal cells. In parallel, either key pathogenic genes lose their epigenetic repressive marks, or counterregulatory genes are silenced by aberrant cytosine methylation.

EPIGENETICS AND MICRORNA

MicroRNA is small noncoding RNA molecules that silence their target genes by transcriptional or translational inhibition. In many conditions, including rheumatic diseases, microRNA expression has been found to be disturbed, with some microRNA upregulated and others downregulated.¹¹⁵ In RA synovial fibroblasts, for instance, expression of microRNA 155, 146a, 203, 323, and 124 was found to be dysregulated.¹¹⁶ MicroRNA is encoded in the genome in intergenic regions and overlapping introns or in the exons of other genes.¹¹⁷ From studies of tumor cells it is known that deletions, translocations, and amplifications often occur in microRNA-encoding regions.¹¹⁸ In addition, approximately 50% of the microRNA-coding genes are estimated to be affected by disturbances in DNA methylation.¹¹⁹ In turn, microRNA can also modulate the expression of genes that are important for the epigenetic machinery. Disturbances in this microRNA consequently lead to epigenetic changes. In SLE, for instance, microRNA 21 and 148a are overexpressed in T cells. Both these microRNA molecules target DNMT1 and thus contribute to the lack of DNMT1 and DNA hypomethylation in lupus T cells.¹²⁰

The microbiome in rheumatic diseases

■ JOSE U. SCHER ■ STEVEN B. ABRAMSON

- Many rheumatic and autoimmune diseases are categorized as complex and polygenic disorders. Genes have a clear role in their pathogenesis, but environmental factors appear to be required for the development of disease.
- Multiple lines of epidemiologic and clinical investigation have implicated several microorganisms in inflammatory rheumatic disorders; however, causation could not be established.
- The microbiome is defined as the totality of microbial communities and their genes in a defined community or biologic niche; the human microbiome is vast and complex and outnumbers the host genome by several orders of magnitude.
- Culture-independent, high-throughput DNA-sequencing technologies—coupled with deeper insight into mucosal immunology—have significantly advanced our understanding of the role of microorganisms in modulating health and disease.
- Germfree and gnotobiotic experiments have provided a deeper understanding of host-microbial interactions and have shown the ability of gut bacteria to induce both local and systemic autoimmunity in genetically predisposed animal models.
- The role of the oral, gut, and skin microbiome in human autoimmunity has recently been recognized as a potential contributor to disease mechanism.

INTRODUCTION

All mammals, including humans, are home to trillions of bacteria from the instant that they are born. Immediately afterward, a massive, complex and dynamic community of microorganisms rapidly begins to populate most cavities and surfaces of our body (including the skin, airways, and genitourinary and gastrointestinal tracts) and coexists with us rather harmoniously for the rest of our lives. This microbiome represents the totality of the ecologic communities of symbiotic, commensal, and pathogenic microorganisms (and their genomes) that we necessarily procure from the environment.¹ This interdependent, synergistic biologic bond is based on a mutually beneficial exchange. Humans provide an appropriate nutritional environment for bacteria, fungi, and viruses, which in return help shape the mucosal immune system, degrade complex polysaccharides, and produce vitamins and other factors essential for our survival.²

Until very recently, however, most of these microorganisms have been all but ignored as determinants of health and disease. Many rheumatic and connective tissue disorders are currently categorized as complex polygenic autoimmune diseases. Despite recent advances in molecular pathogenesis and treatment, most arthritides can be ameliorated but not cured, and their etiology remains elusive. Genes have a clear contribution to susceptibility, but these genetic effects appear to require environmental factors to explain differences in incidence of the disease.

Characterizing the microbiota inhabiting humans is now possible because of exponential advances in bacterial DNA-sequencing technologies. Largely as a result of the National Institutes of Health (NIH) Human Microbiome Project (HMP) and the European Metagenomics of the Human Intestinal Tract (MetaHit) consortium, an almost complete catalogue of intestinal, periodontal, and skin microbial communities is now in existence.^{3,4} This knowledge, coupled with renewed interest in mucosal immunology, provides important insight suggesting that the human microbiome

represents an environmental factor capable of influencing autoimmune disease manifestations.

THE MICROBIOME

Humans undergo embryonic maturation within a naturally protected, sterile habitat. Immediately after birth, vaginal- or skin-derived bacteria (depending on the delivery technique) colonize the neonate's gastrointestinal tract and other body surfaces.⁵ For several months there is a period of relative taxonomic instability. Over time, however, phylogenetic richness and species diversity increase, and by the end of the first year of life, particularly with the introduction of solid foods, the gut microbiota expands, stabilizes, and adopts the characteristics of the adult communities.⁶ At this stage the human microbiome is quantitatively vast and complex. In total, 100 trillion microorganisms live in our body spaces and outnumber the amount of human cells by a factor of 10⁷. The adult human gut alone contains on average 2 kg of bacteria, whose collective genome encodes approximately 3.3 million different genes—100 times more than that of its human host. Although more than 1000 different species from a dozen divisions colonize the gastrointestinal tract, the microbiome of healthy humans is dominated by four major bacterial phyla: Firmicutes, Bacteroidetes (which combined represent about three quarters of the total gut community), and to a lesser degree, Proteobacteria and Actinobacteria.⁸ More importantly, humans can be clustered into three groups (or enterotypes) according to the composition of their gut microbiome.⁹ In healthy individuals from industrialized nations, these enterotypes appear to be independent of host factors, thus arguing for the existence of three stable core human microbiomes.¹⁰

MUCOSAL BARRIERS AND HOST-IMMUNE INTERACTIONS

Physiologic intestinal inflammation and homeostasis in health

Dietary patterns and antibiotic use are certainly able to alter the composition of the microbial community in the intestine.¹¹ However, the mechanism by which the microbiome is selected, established, and maintained within a given individual remains uncertain. Nevertheless, the symbiotic processes and bidirectional crosstalk between the microbiome and host immune system are becoming better understood. Indeed, the idea that commensal bacteria are merely a group of passive organisms that obtain nutritional benefit at the host's expense has become untenable. Compelling recent evidence has demonstrated that cells from both the innate and adaptive immune systems in the lamina propria actively cooperate to maintain a state of homeostasis (Fig. 19.1, left panel). In this healthy state, a massive amount of antigenic material derived from the diet and commensal flora is actively tolerated by mucosal-associated lymphoid tissue to mutually benefit the microbiota and its host.¹² Through evolution, several biologic check points have been established to keep these two “biologic universes” separate and prevent microorganisms from accessing the lamina propria and, eventually, the peripheral organs and tissues. A physicochemical and immune barrier represents the first line of defense. A thick mucus layer,¹³ enteric antimicrobial proteins,¹⁴ and high levels of secretory immunoglobulin A¹⁵ are all designed to prevent a flood of undesired flora (or any of their components) into the host. Tightly adherent epithelial cell columns that further contain bacterial invasion provide a second protective strategy. Enterocytes not only function as a strict anatomic boundary but also have

Fig. 19.1 (Left panel) In the healthy state, balanced host-microbial interaction is essential for maintenance of homeostasis. A thick mucus layer, epithelial cells, and secretory IgA form a physicochemical barrier that prevents direct contact with gut-associated lymphoid cells, which constantly survey the contents of the intestinal lumen and eliminate undesired antigens. Commensal bacteria such as *Bacteroides fragilis* can activate pro-tolerogenic machinery. A specific cell wall component, polysaccharide A (PSA), is sufficient to induce activation of regulatory T cells (Tregs), production of interleukin-10 (IL-10), and repression of type 17 helper T cells (Th17) to avoid uncontrolled inflammation. (Right panel) When either genetic, dietary, or environmental factors alter the balance in composition of the microbiota, a state of dysbiosis ensues. Potentially harmful bacteria (such as segmented filamentous bacteria or *Lactobacillus*) predominate and promote local activation and expansion of proinflammatory cells (Th17 cells, Th1 cells, and others) through several molecules (such as adenosine-5'-triphosphate [ATP], serum amyloid A [SAA], or CCL5 signaling). These autoreactive T cells migrate to peripheral immune compartments and activate B cells to differentiate into autoantibody-producing plasma cells. These cells and antibodies then migrate to synovial tissue, where the inflammatory cascade is amplified through the activation of effector components, including macrophages, fibroblasts, osteoclasts, cytokines, and proteinases. If self-perpetuating, this process can lead to arthritis and joint destruction. IFN- γ , interferon- γ ; TNF, tumor necrosis factor. (Adapted with permission from Scher JU, Abramson SB. *The microbiome and rheumatoid arthritis*. *Nat Rev Rheumatol* 2011;7:569-78.)

functional antimicrobial properties.¹⁶ These cells produce a variety of bactericidal proteins such as defensins, cathelicidins, and C-type lectins. Furthermore, epithelial cells express Toll-like receptors (TLRs) in their cellular membrane that allow recognition of pathogen-associated molecular patterns in microorganisms, activation of the signaling adaptor molecule MyD88 (myeloid differentiation primary-response protein 88), and induction of downstream inflammatory responses. If still insufficient, the intestinal lamina propria harbors the largest and most varied immune armamentarium

in mammals. Bacterial proteins and surface molecules such as lipopolysaccharides and other microbe-associated molecular pattern factors interact with TLRs and related pattern recognition receptors in the host innate immune cells.¹⁷ Dendritic cells, macrophages, and natural killer cells continuously survey the lumen to process and phagocytose antigens to trigger an appropriate response.

What ultimately defines this homeostatic state between the host and microbiome is a delicate balance in the type and predominance of CD4⁺ T

cells in the lamina propria.¹⁸ A necessary state of “physiologic” gut mucosal inflammation is driven by a permanent but low-level activity of effector cells, including the helper T cells Th1, Th2, and Th17 and their respective signature cytokines interferon- γ , interleukin-4/13 (IL-4/13), and IL-17/22. Regulatory T cells (Tregs), a tolerogenic subset of T cells, produce IL-10 and transforming growth factor- β to proactively counterbalance the potentially exaggerated proinflammatory effects. A fundamental aspect in maintenance of this equilibrium directly relates to the way that the adaptive immune system reacts. Recent paradigm-changing work in mucosal immunology has altered the way in which we understand the dichotomy between innate and adaptive immunity.¹⁹ Surprisingly, even a single intestinal commensal taxon is sufficient to activate CD4+ T cells and shift the balance toward proinflammatory or antiinflammatory responses. Segmented filamentous bacteria (SFBs), commensal gram-negative anaerobes, are able by themselves to activate Th17 cells,²⁰ whereas a specific polysaccharide of *Bacteroides fragilis*—polysaccharide A (PSA)—can stimulate Tregs and promote broad tolerogenic effects through the TLR2 signaling pathway.²¹ These Treg-inducing properties have also been demonstrated for indigenous gut *Clostridium* species.²²

Dysbiosis as a trigger for autoimmunity

An imbalance in the composition of the microbiota (a state called *dysbiosis*) may ensue if potentially pathogenic bacteria expand or beneficial bacteria become less abundant (Fig. 19.1, right panel).¹⁹ This leads to an alteration in the local immune response, typically dominated by proinflammatory cells and their products. When this reaction is self-regulated, the result is beneficial for both the host and the microbiome since detrimental microorganisms are eliminated. When this state of dysbiosis perpetuates, uncontrolled local inflammation is expected, as has been demonstrated in the case of inflammatory bowel disease (IBD; see later). However, the notion that an altered microbiome could influence systemic immune activation (or even lead to distal extraintestinal autoimmunity) is novel. Several studies have now shown that unique commensal species can initially affect the local adaptive immune response and subsequently trigger (or prevent) tissue-specific systemic autoimmunity. In experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis, manipulation of the gut microbiome exacerbates the incidence and severity of EAE.^{23,24} In the non-obese diabetic mouse model of type 1 diabetes, colonization by commensal microbes reduces pancreatic inflammation and autoantibody production and abrogates disease.²⁵

RESEARCH METHODS FOR STUDY OF THE HUMAN MICROBIOME

The vast majority of existing microorganisms simply cannot be isolated in culture, either because they are fastidious growers or because of a lack of understanding of their nutritional or oxygen requirements. This leaves about 80% of all bacteria unidentified. Recent advances in DNA-sequencing technologies now permit these microbiologic challenges to be circumvented. A component of prokaryotes’ small ribosomal subunit, 16S ribosomal RNA (16S rRNA), is now used to establish phylogenetic analyses in microbiome studies.²⁶ This gene is uniquely found in bacterial cells and has highly conserved primer binding sites, and it is therefore very useful for determining which members of a given community are present without prior knowledge. The gene is also advantageous because it does not amplify human DNA. Yet at the same time, the 16S gene possesses several hypervariable regions that provide specific sequences unique to each species, thereby allowing extensive bacterial taxonomic identification without the need for culture.^{27,28}

Bacterial DNA is typically extracted from the human samples of choice and further amplified by using universal 16S primers. Pyrosequencing is then performed and the sequences obtained are aligned, trimmed, and subsequently classified. Ultimately, this approach provides an overall understanding of which bacterial species are represented in a given community and their relative abundance. Such studies have, for example, established associations among patients with autoimmune disorders (i.e., psoriasis, IBD, and type 1 diabetes). This methodology, though useful for establishing correlative associations, does not consider the functional enzymatic capabilities of the microbiome. The physiologic activities of these “second genomes” can provide insight into mechanisms of disease as well.²⁹ For example, a seminal study comparing the gut microbiota of monozygotic twins discordant for obesity revealed a similar taxonomic content among groups. However, there was a significant (and constant) variation in enzymatic pathways that differentiated obese from lean individuals.³⁰ This approach, known as whole-genome shotgun sequencing, complements the 16S studies

and requires the complete DNA sequencing of genes found in a given community. Beyond functionality, alignment of full genomes can also provide knowledge about potential islands of pathogenicity or even antigenic structures embedded in the microbiome, which may in turn help in the discovery of factors triggering local and systemic autoimmunity.

Aside from DNA sequencing, the study of proteomics and metabolomics is also of high relevance for understanding microbiome behavior and its impact on the host. Unique molecular components of bacteria rather than entire genetic or enzymatic structures may be sufficient to alter the mammalian immune response. This has been illustrated recently in the case of the periodontopathic bacterium *Porphyromonas gingivalis* and its relationship with the pathogenesis of rheumatoid arthritis (RA). *P. gingivalis*-derived enzymes such as α -enolase seem to be sufficient for triggering inflammatory joint disease in predisposed murine models³¹ (see the RA microbiome section). Similarly, PSA-containing *B. fragilis* (but not the PSA knockout variant) is able to protect against EAE, an animal model of multiple sclerosis.³² This is of importance because it promotes the notion that (at least hypothetically) specific parts of unique microorganisms could serve as biomarkers of autoimmune disease or even be the target of therapeutic approaches.

In 2007 the NIH established the HMP³³ and the European Commission launched the MetaHit consortium. Their central objective, perhaps complementary to the Human Genome Project, is to characterize the microbial communities found at several different sites on the human body and to analyze the role of these microbes in human health and disease.

THE MICROBIOME IN ANIMAL MODELS OF INFLAMMATORY ARTHRITIS

The physiologic and metabolic importance of the gut microbiome and its role in maturation of the host immune system has been studied with the use of gnotobiotic experiments. In a gnotobiotic animal, only certain known strains of bacteria and other microorganisms are present. Because these gnotobionts are normally reared in a sterile (germfree [GF]) or microbially controlled environment, they are a unique tool to study symbiotic relationships between a host and one or more microorganisms of interest.³⁴ In a similar experimental fashion, several studies have assessed the influence of intestinal bacteria as triggers for inflammatory arthritis (Fig 19.2). Since the 1970s, multiple animal models have been described as being susceptible to arthritis only when exposed to microorganisms, particularly those from the intestinal flora. The original report showed a protective effect of germs in an adjuvant-induced arthritis rat model in which severe inflammatory arthritis developed in the totality of animals raised in a GF state, as opposed to a significantly lower incidence in conventionally reared rats.³⁵ Research involving the streptococcal cell wall-induced rat arthritis model illustrates another classic example of these interactions. In this model too, conventionally raised animals are typically resistant to joint inflammation, whereas GF rats become susceptible to arthritis.³⁶

Many more studies using similar approaches were reported in the 1980s. These studies revealed that specific gram-negative enterobacteria were either protective³⁷ or inducers³⁸ of inflammatory arthritis in GF rats, thus raising the possibility of the intestinal microbiota as a triggering factor. In one of the most elegant set of experiments in the field of spondyloarthritis, Taurog and colleagues³⁹ described the need for commensal (and not necessarily pathogenic) intestinal bacteria in the development of both local intestinal inflammation and peripheral arthritis in HLA-B27 transgenic rats (a spontaneous model of spondyloarthritis in which multiple copies of HLA-B27 and human β_2 -microglobulin transgenes are microinjected). In GF rats, in turn, signs of mucosal or joint damage do not develop. Taken together, these results provided initial support for the hypothesis of an interrelationship between alterations in the gut microbiome (dysbiosis) and the development of systemic inflammatory arthritis. The original literature was indeed ambiguous about whether the intestinal flora was protective of or detrimental to joint physiology, but mechanistic insight had been scarce. Clearly, the host’s genetic background and even gender may modulate susceptibility to arthritis after exposure to a given microbiome. This was elegantly illustrated in a recent study of collagen-induced arthritis in mice in which HLA genes were differentially expressed.⁴⁰ Using 16S rRNA gene pyrosequencing, arthritis-susceptible HLA-DRB1*0401 mice were found to have an intestinal microbiota dominated by a *Clostridium*-like bacterium, whereas the guts of *0402 mice were enriched with members of the Porphyromonadaceae family and *Bifidobacterium* genus. Even though DRB1*0402 mice contained a dynamic sex- and age-influenced gut microbiome, only DRB1*0401 mice had altered mucosal immune function and increased gut permeability.

Fig. 19.2 Gnotobionts are animals that are kept germfree (GF) until known specific microorganisms are introduced in a controlled setting. Use of this experimental approach has advanced our understanding of how local changes in the intestinal microbial community (dysbiosis) are capable of producing an imbalance in the proinflammatory and antiinflammatory immune response and ultimately trigger autoimmunity at distal sites. Segmented filamentous bacteria (SFB) are sufficient to activate lamina propria type 17 helper T cells (Th17) cells in the K/BxN model of inflammatory arthritis. These cells migrate to the periphery, produce interleukin-17 (IL-17) (their signature cytokine), and stimulate plasma cells to produce arthritogenic autoantibodies. However, when kept in GF conditions, arthritis does not develop in these animals. *Lactobacillus* is also a proarthritogenic microorganism in the *IL1rn*^{-/-} model. An increase in Th17 cell activity and a decrease in regulatory T cell (Treg) function are key to the development of joint inflammation. Colitis or arthritis does not develop in the HLA-B27 transgenic rat in the GF state. Inflammation is activated by gut commensals such as *Bacteroides*. AA, adjuvant arthritis; CIA, collagen-induced arthritis; TLR2, Toll-like receptor 2. (Adapted with permission from Scher JU, Abramson SB. The microbiome and rheumatoid arthritis. *Nat Rev Rheumatol* 2011;7:569-78.)

Since the late 2000s, the use of gnotobiotic mice has expanded our knowledge about the role of the gut microbiome in inflammatory arthritis (see Fig. 19.2). Autoimmune T-cell-mediated arthritis develops spontaneously in IL-1 receptor antagonist knockout (*IL1rn*^{-/-}) mice, for example, unless the animals are kept under GF conditions. When these mice are monocolonized with a strain of the commensal *Lactobacillus bifidus*, rapid and severe arthritis develops, comparable to that of conventionally raised mice.⁴¹ An imbalance in the Treg/Th17 cell response and subsequent TLR activation seems to explain the mechanism behind *Lactobacillus*-triggered arthritis in this model.

The K/BxN T-cell receptor transgenic mouse is another well-studied model of inflammatory arthritis that is caused by autoreactive T-cell-driven production of autoantibodies against glucose-6-phosphate isomerase.⁴² Here again, the incidence and severity of arthritis are decreased in GF animals, largely because of lower activation of peripheral Th17 cells. However, the introduction of a single gut-residing commensal SFB restores the disease phenotype,⁴³ and arthritis is abrogated when the mice are treated with SFB-targeting antibiotics from birth. Gut and joint inflammation in the SKG mice, another Th17-driven model characterized by a single point mutation in ZAP-70, is also flora dependent, although mostly fungal in origin.⁴⁴

Taken together, these data suggest that a particular intestinal microbiota is required to trigger (if not drive) systemic autoimmunity and subsequent inflammatory arthritis in animal models. It also ascribes to the notion that a state of dysbiosis may require genetic host susceptibility, as illustrated by the inability of wild-type animals to mount an inflammatory response even in the presence “proarthritogenic” gut flora.

THE MICROBIOME IN HUMAN INFLAMMATORY ARTHRITIS

The relevance of enteropathic arthritis to human rheumatic disease can be found in the pathogenesis of several arthritides. Spondyloarthritis, particularly enteric reactive arthritis and IBD-related arthropathy, are the most prevalent examples. Other notable entities include jejunoileal bypass-arthritis syndrome, celiac disease, the microscopic colitis spectrum, and Whipple disease, which are discussed in their respective chapters. The skin,

gut, and periodontal microbiomes have also been implicated in the etiopathogenesis of psoriasis and RA.

Spondyloarthritis

Spondyloarthritis (SpA) is a continuum of a spectrum of multiple related but phenotypically distinct disorders, including psoriatic arthritis (PsA), reactive arthritis, IBD-related arthropathy, and ankylosing spondylitis (AS).^{45,46} There is a constellation of several potential clinical manifestations ranging from axial and peripheral arthritis to psoriasis, uveitis, and bowel inflammation. The link between joint and gut inflammation in the SpA spectrum is well established in both murine models (i.e., HLA-B27 transgenic rats)^{46,47} and humans. The strongest association has been found between IBD and AS—AS develops in as many as 16% of patients with IBD, almost 50% of whom exhibit some compromise of their sacroiliac joints.⁴⁸ Conversely, up to two thirds of SpA patients show signs of subclinical microscopic gut inflammation, most notably in 60% of those with AS and 90% of those with enterogenic reactive arthritis.⁴⁹ This mucosal inflammation affects both the terminal ileum and the colon and could be either acute (bacterial enterocolitis-like) or chronic (Crohn-like). The acute form is associated with transient arthritis, whereas the chronic type is seen in patients with persistent joint inflammation who are at higher risk for full-blown IBD. Notably, gut inflammatory changes fluctuate with the activity of arthritis and vice versa.⁵⁰ Interestingly, circulating antibodies against the enteric microbes present in IBD patients, such as anti-I2, are also found in the plasma of AS patients.⁵¹ Moreover, the efficacy of sulfasalazine for both IBD and SpA (a drug that is poorly absorbed from the gut) represents another manifestation of the gut-joint linkage. Using low-throughput denaturing gradient electrophoresis and polymerase chain reaction (PCR) methods, one study showed a significant decrease in intestinal sulfate-reducing bacteria (i.e., *Desulfovibrio* spp.) in AS patients versus controls,⁵² an alteration also found in IBD patients. This has led to the use of a cocktail of commensal bacteria for the treatment of SpA. Even though this randomized clinical trial did not demonstrate significant benefit over placebo,⁵³ there is a clear need for further diagnostic and therapeutic exploration with novel DNA-sequencing techniques and more defined microbial communities.

Inflammatory bowel disease–related arthropathy

IBD is a spectrum of autoimmune disorders affecting the gastrointestinal tract, more commonly the colon and small intestine. The major types of IBD are Crohn disease (CD) and ulcerative colitis (UC). Concomitant nonaxial joint inflammation develops in about a third of all patients. Two forms of peripheral arthropathy have been described. Type I is typically found in UC, is oligoarticular in nature, and usually follows IBD activity. Type II IBD–related arthritis tends to be chronic and polyarticular and has a course independent of that of gut mucosal inflammation.⁵⁴ In addition, as discussed, axial arthropathy is significantly higher in those with IBD. AS is reported in 1% to 16% of patients, whereas asymptomatic sacroiliitis occurs in up to 45% of patients with IBD. Although no single taxon has ultimately been implicated, most reports confirm a state of dysbiosis with an overall decrease in phylogenetic diversity. Both CD and UC patients have decreased biodiversity, a lower proportion of Firmicutes, and an increase in Gamma-proteobacteria.⁵⁵ Microbial clades differentially abundant in IBD include *Roseburia* and *Phascolarctobacterium* (decreased in CD and UC) and Ruminococcaceae (decreased in CD only), along with a significant increase in Enterobacteriaceae (specifically, *Escherichia* and *Shigella* genera).⁵⁶ A dramatic reduction in the relative abundance of Firmicutes, one of the two major phyla along with Bacteroidetes, has consistently been reported. Several members of this group are known producers of potent antiinflammatory short-chain fatty acid metabolites, such as acetate (Ruminococcaceae) and butyrate (*Roseburia*). In CD patients, a specific decrease in *Faecalibacterium prausnitzii* (another potent butyrate producer) has also been described and validated.⁵⁷ Permanent reductions in all of these clades, coupled with an increase in pathobionts from the *Escherichia/Shigella* group, may ultimately have functional consequences on the ability of the host to repair the gut epithelium and regulate local inflammatory responses. Whether these IBD-associated alterations in the gut microbiome differ in patients with articular manifestations is unknown. Intriguingly, mice deficient in any step of the inflammasome pathway involving NLRP6, ASC, caspase-1, or IL-18 show an alteration in gut microbial ecology. This shift in microbiota is dominated by members of the Prevotellaceae family and is associated with an IBD-like phenotype that is transmissible to cohoused wild-type mice.⁵⁸

Psoriasis and psoriatic arthritis

PsA is a chronic inflammatory arthritis that affects individuals with psoriasis of the skin (Ps). The prevalence of Ps is approximately 2% to 3% in the general population, whereas the incidence of PsA in patients with Ps is about 30%.⁵⁹ For reasons that are unclear, PsA typically occurs after the onset of skin disease. The pathogenesis of PsA remains poorly understood, and the current paradigm posits that in the presence of strong genetic risk factors (e.g., major histocompatibility complex class I molecules such as HLA-B*27 and B*39),⁶⁰ PsA will develop in individuals with Ps after exposure to currently unidentified environmental factors and that arthritogenic antigens may trigger innate immune responses that secondarily drive adaptive immunity and lead to systemic and joint inflammation. Although genes are important in the pathogenesis of PsA, there are apparent limitations to this contribution, as demonstrated by a modest concordance rate in first-degree relatives and monozygotic twins. Proposed environmental triggers have included viruses, vaccinations, bacterial infections, trauma, and stress. PsA has specifically been associated with changes in the gut microbiota. As described, PsA develops in HLA-B27–overexpressing rats only in the presence of intestinal microbes, whereas subclinical gut mucosal inflammation has also been found in patients with active PsA,⁶¹ mostly in those with predominantly axial disease. Furthermore, a history of infections that required antibiotic treatment was associated with the occurrence of arthritis in patients with Ps.⁶² Most recently it was shown that dendritic cells from PsA patients (but not from those with Ps) have an impaired immune response to bacteria.⁶³ These data reinforce the notion of an altered bacterial clearance mechanism in PsA that eventually leads to chronic systemic inflammation in joints, entheses, skin, and even the gut.

The human skin microbiome has also recently been studied with high-throughput DNA-sequencing techniques. Surprisingly, its diversity is much greater than anticipated from the original culture-based reports.⁶⁴ Four different phyla predominate: Actinobacteria, Firmicutes, Bacteroidetes, and Proteobacteria. However, the relative abundance of the skin microbiome is directly dependent on the physiologic condition of a given topographic region and is associated with factors such as moisture (high abundance of *Staphylococcus* and *Corynebacterium* species) and sebaceous content (predominance of *Propionibacterium* spp.). Poststreptococcal psoriasis, which could evolve into chronic psoriasis in 40% of cases, is a well-established

bacterial-associated mechanism.⁶⁵ Moreover, the composition of the cutaneous microbiota in patients with psoriasis was studied recently.⁶⁶ Striking differences could be demonstrated at both the phylum and species level. For instance, Actinobacteria and *Propionibacterium acnes* were both underrepresented in untreated psoriatic plaques when compared with unaffected skin from the same psoriasis patients and normal controls. This may be the result of an inhospitable microenvironment for these organisms, or equally possible, they may play a protective role against psoriasis. The role of the gut and cutaneous microbiota in the passage from Ps to PsA is an attractive hypothesis and a matter of intense research. It is conceivable that alterations in microbial composition herald (or even promote) the advance from skin disease to a more disseminated phase in which joints and entheses are also affected.

Rheumatoid arthritis and the microbiome

Since the discovery of the microscope and microorganisms by Antony van Leeuwenhoek in the 18th century, successive hypotheses attempted to link the oral and intestinal microbiome with the etiology of RA. Notably, Sir William Osler described *arthritis deformans* as being due to tuberculosis,⁶⁷ the *focal sepsis* hypothesis attributed periodontal flora as the cause of RA,⁶⁸ and the *toxemic factor* theory proposed that substances produced by intestinal microorganisms are ultimately responsible for the joint inflammation in rheumatoid patients.⁶⁹ Paleopathologic and epidemiologic evidence, though debatable, suggests that RA is a transmissible New World disease that spread to the rest of the planet after the conquest.⁷⁰ This is based on the lack of skeletal remnants with RA-like erosions outside the Americas and a higher prevalence of the disease in Native Americans than in other populations. Moreover, until very recently, the incidence of RA appeared to be declining.⁷¹ Because genetic changes occur over several generations, this decrease has been attributed to a possible “birth cohort” effect or “hygiene hypothesis.” These theories propose a role for an infectious agent that was presumably highly prevalent a century ago but has been slowly eradicated by introduction of the modern lifestyle and dietary modifications. Exposure to this agent by subsequent generations may therefore have decreased along with the incidence of the disease. Several clinical reports have implicated specific pathogenic microorganisms as triggers for RA, mostly through indirect evidence (serologic and PCR methods) and circumstantial observations. These microorganisms include several viruses and retroviruses, bacteria, and mycoplasmas (see Chapter 107). However, a precise causal effect could not be established.

The intestinal microbiome in rheumatoid arthritis

The idea that intestinal microorganisms are associated with the development of RA is not novel. Classic examples at the beginning of the 20th century include the albuminous putrefaction therapies of Andrews and Hoke and the toxemic factor hypothesis of Carl Warden.

Beyond convincing animal model data on the role of intestinal bacteria in RA-like disease, there is also evidence that therapeutic regimens seemingly targeting the enteroarthropathy connection work in the clinic. Many of these drugs have been classified as disease-modifying antirheumatic drugs (DMARDs) and are still in use today. This notion was originally developed in the 1940s, when sulfasalazine became the first rationally designed compound for the treatment of rheumatic diseases. Because RA was thought to be caused by streptococci found in milk,⁷² sulfasalazine was created in a deliberate effort to combine a sulfonamide antibiotic (against enteric bacteria) with a salicylate (as antiinflammatory agent) through an azo bond.⁷³ Sulfasalazine, as well as the antimalarial agent hydroxychloroquine, are currently used for mild cases of RA. Moreover, triple DMARD therapy (a combination of sulfasalazine, hydroxychloroquine, and methotrexate) remains one of the few first choices for all patients with RA who have poor prognostic features and moderate or high levels of disease activity, regardless of disease duration,⁷⁴ and it appears to be equivalent in efficacy to the combination of methotrexate and a biologic agent for early RA.⁷⁵ Furthermore, tetracycline antibiotics have also been proved to be efficacious in the treatment of early seropositive RA,⁷⁶ which has led to the approval of minocycline as a DMARD. Despite these encouraging clinical outcomes, the underlying mechanisms of action for all these drugs—particularly their specific antibiotic properties—have never been completely elucidated.

The community composition of intestinal bacteria in patients with RA has been studied with low-throughput technologies. Via gas-liquid chromatography or limited oligonucleotide probing, RA patients were found to have a decrease in *Bacteroides* groups in comparison to controls.⁷⁷ These approaches, however, remain inadequate and nonspecific for characterization of the entire gut microbiota. Efforts using high-throughput DNA sequencing are currently under way.⁷⁸

The oral microbiome in rheumatoid arthritis

At the turn of the 20th century, the widely prevalent oral sepsis hypothesis led to the use of teeth extraction as a widespread treatment of RA. It lasted for several decades and was eventually deemed ineffective. In the last decade, a vast body of published literature has shown epidemiologic associations between the presence of periodontal disease (PD) and RA. PD was more common and severe in patients with RA than in those with osteoarthritis.⁷⁹ In another study, subjects with RA had an eightfold increased likelihood of periodontitis in comparison to controls.⁸⁰ Others have found a less robust correlation, thus suggesting that study methodologies and the definition of PD have been variable.

Multiple lines of investigation have also implicated *P. gingivalis*, a common periodontopathic bacterium, as a possible triggering factor for joint inflammation.⁸¹ *P. gingivalis* is a gram-negative anaerobe that contains a unique enzyme—peptidyl arginine deiminase (PADI)—that is capable of citrullinating arginine peptide residues in a calcium-dependent posttranslational modification process. According to this model, these citrullinated residues turn into neopeptides that are recognized by antigen-presenting cells in the appropriate genetic context (i.e., HLA); this leads to the activation of T and B cells, which ultimately stimulates the production of anti-citrullinated peptide antibodies (ACPAs) by plasma cells and unfolding inflammatory responses within the joint. Evidence to support this model is derived from *in-vitro* and *in-vivo* studies. PADI-sufficient *P. gingivalis*—but not other periodontal bacteria or a PADI knockout strain—is able to citrullinate human fibrinogen and α -enolase.⁸² Intriguingly, in susceptible DR4-IE transgenic mice, both autoimmunity and inflammatory arthritis develop when immunized with *P. gingivalis* enolase (both citrullinated or uncitrullinated), thus suggesting a pathogenic role in the initiation of disease.³¹ Citrullination of proteins occurs as a part of physiologic cellular processes, particularly in apoptosis. The joints of patients with RA, however, have abnormally high levels of both citrullinated proteins and ACPAs.⁸³ There is

limited evidence that ACPAs are responsible for the initiation of RA since these antibodies (along with rheumatoid factor) can be found several years before any clinical manifestation become evident.⁸⁴ Several recent human studies have established a positive serologic correlation between *P. gingivalis* exposure, ACPA titers, and RA,^{85,86} with first-degree relatives demonstrating an intermediate antibody profile when compared with healthy controls.⁸⁵ The first study that directly looked at the presence of oral microorganisms was recently conducted and used multiplexed pyrosequencing to compare the bacterial composition of the subgingival microbiota in those with new-onset, DMARD-naïve RA and controls.⁸⁷ Notably, RA patients exhibit a high prevalence of PD at disease onset, and their subgingival microbiota is similar to that of patients with chronic RA and healthy subjects with comparable PD severity. Overall, *P. gingivalis* is found in 55% of RA patients versus 27% of controls, thus suggesting a potential common pathway for RA and PD and a potential role for *P. gingivalis* in a subset of RA patients.

CONCLUSION

New DNA-sequencing technologies and experimental approaches have brought novel insight into the potential mechanisms of disease behind autoimmune processes. It is now possible to taxonomically characterize thousands of bacteria (and their function) in exquisite detail. Animal models of inflammatory arthritis have shown the capacity of specific oral and intestinal commensal bacteria to activate proinflammatory cells, which then initiate and perpetuate deleterious effects in the joint. The clinical implications of these discoveries, along with the notion that humans harbor distinct enterotypes, open a new perspective in rheumatic and autoimmune research. Identification of “arthritogenic” commensal organisms could provide insight into the “in-virionmental” trigger of these diseases and lead to a new understanding of disease pathogenesis that could result in novel preventive therapies.

Tissue destruction and repair

■ TIM E. CAWSTON ■ D.A. YOUNG ■ DREW D. ROWAN

- Cartilage is made up of collagens, proteoglycans, and minor glycoproteins. Bone consists of a mineralized collagen matrix. Both tissues can be degraded by active proteinases.
- Different classes of proteinases play a part in connective tissue turnover, but the proteinase that predominates varies with different tissues and the resorptive situation.
- Matrix metalloproteinases (MMPs) are produced in proforms and, once activated, can degrade connective tissue. MMPs are inhibited by tissue inhibitors of metalloproteinases (TIMPs), and the balance between active MMPs and TIMPs determines the extent of degradation. Pro-MMPs can be activated by metalloproteinases and serine proteinases. ADAM (a disintegrin and metalloproteinase) and ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) proteinases are also upregulated in diseased joints and cleave proteoglycans. Serine proteinases have likewise been implicated in cartilage breakdown, and cysteine proteinases initiate collagen breakdown in bone.
- Various cytokines and growth factors, alone or in combination, inhibit matrix synthesis and stimulate proteinase production and matrix destruction. Tissue destruction occurs in both rheumatoid arthritis and osteoarthritis.
- Some growth factors increase the synthesis of matrix and proteinase inhibitors. Growth factor combinations can be used in conjunction with stem cells and chondrocytes within artificial matrices to promote the repair of small cartilage defects in large joints.

INTRODUCTION

Cartilage and the underlying subchondral bone are destroyed in severe cases of arthritis, and this limits normal joint function. Cartilage contains different types of collagen, which are composed of rod-shaped molecules that aggregate in staggered arrays to form cross-linked fibers that give connective tissue strength and rigidity.¹ Entrapped within these collagen fibers are the proteoglycans,² predominantly aggrecan, which consists of three globular domains interspersed with heavily glycosylated and sulfated polypeptide. In the presence of hyaluronic acid, these form highly charged aggregates, attract water into the tissue, and allow cartilage to resist compression. Chondrocytes in normal adult cartilage maintain a steady state in which the extent of matrix synthesis equals that of degradation. Any change in this steady state will affect the functional integrity of cartilage. During growth and development, synthesis of matrix components exceeds degradation, whereas in pathology there is an increase in the rate of degradation that is often associated with a reduction in matrix synthesis.

The primary cause of cartilage and bone destruction in the arthritides is elevated levels of active proteinases, secreted from a variety of cells, that degrade collagen and aggrecan. The sources of these proteinases depend on the type of disease. In osteoarthritis (OA), the proteinases produced by chondrocytes play a major role. In contrast, in a highly inflamed rheumatoid joint, chondrocytes, synovial cells, and inflammatory cells all contribute to the proteolytic loss of tissue matrix.

Joint tissues are capable of repair; although aggrecan can be readily resynthesized, replacement of collagen after its destruction is more difficult.³

A variety of growth factors and cytokines present in the joint are able to promote matrix synthesis, and these factors have been studied to determine whether cartilage and bone defects can be repaired *in vivo*.

PROTEOLYTIC PATHWAYS OF CONNECTIVE TISSUE BREAKDOWN

Extracellular matrix proteins are broken down by different proteolytic pathways. The five main classes of proteinases⁴ are grouped according to the chemical group that participates in the hydrolysis of peptide bonds. Cysteine and aspartic proteinases are predominantly active at acidic pH and act intracellularly; threonine proteinases, the proteasome being the most characterized, also act intracellularly at nearly neutral pH; and the serine proteinases and metalloproteinases, active at neutral pH, mostly act extracellularly. Other enzymes, such as elastase, are stored and released when neutrophils are stimulated. Some enzymes, such as furin, may not participate in the proteolysis of matrix proteins but activate proenzymes that subsequently degrade the matrix. Membrane-bound proteinases are associated with cytokine processing, receptor shedding, and removal of proteins that are responsible for cell-cell or cell-matrix interactions.

The complete repertoire of human proteases (defined as the degradome)⁵ comprises approximately 569 proteinases, and all classes of proteinases have roles in the turnover of connective tissue. One proteinase pathway may act in concert with or precede another, and the pathway that predominates varies with different resorptive situations. Turnover of the extracellular matrix often involves complex interactions between different types of cells. The osteoid layer in bone is removed by osteoblast metalloproteinases before the attachment of osteoclasts, which secrete predominantly cysteine proteinases such as cathepsin K. These proteinases degrade bone matrix after removal of the mineral. An intricate series of interactions between T cells, macrophages, synovial fibroblasts, and chondrocytes occur in the rheumatoid joint. In septic arthritis, both serine proteinases and metalloproteinases released from neutrophils exceed the local concentration of inhibitors, which results in rapid removal of the cartilage matrix from the joint cavity. In OA, the inflammation is typically less marked but nevertheless is thought to contribute to pathology.⁶ Other mechanisms also contribute to joint tissue destruction, especially in OA, including abnormal mechanical loads inducing mechanosensitive genes and age-related changes in the cartilage matrix (such as advanced glycation end products) altering cellular responses by engaging alternative receptors (e.g., Toll-like receptors) and resulting in the expression of different genes.

EXTRACELLULAR PROTEOLYSIS—NEUTRAL PROTEINASES

Matrix metalloproteinases

The matrix metalloproteinase (MMP) family, when activated and acting collectively, can degrade all the components of the extracellular matrix. MMPs are zinc-dependent endopeptidases, and all contain common domains (Fig. 20.1).⁷ All are produced as latent (inactive) proenzymes, and proteolytic loss of the propeptide leads to activation. The membrane-type MMPs (MT-MMPs) and stromelysin-3 (MMP-11) have a short peptide insert between the propeptide and the N-terminal domain, a sequence recognized by furin, a serine proteinase located in the Golgi apparatus; these MMPs are therefore secreted as active enzymes. Zinc is present at the catalytic center within the N-terminal catalytic domain, which is joined to the C-terminal

Fig. 20.1 All matrix metalloproteinases (MMPs) contain a similar domain structure with a zinc-binding domain (yellow), and most contain the C-terminal domain (blue). All are secreted with a propeptide (purple) that maintains the latency of the MMP by a conserved cysteine binding to the active site zinc. Other groups of MMPs build on this core structure. The gelatinases have additional domains inserted (green). The membrane-type MMPs (MT-MMPs) have a transmembrane domain (pink) that locates the MMP at the cell surface. The MT-MMPs and stromelysin-3 have a sequence of basic amino acids inserted between the prodomain and catalytic domain that are specifically recognized by furin, a serine proteinase that activates these enzymes intracellularly. Varying the domains ensures that individual MMPs can bind to the matrix components that they cleave.

hemopexin domain by a flexible linking peptide. For efficient collagenolysis, cooperation between the catalytic domain and an exosite in the hemopexin domain that specifically binds the C-terminal to the scissile bond is critical for conferring substrate specificity.⁸ MMP-8 and MMP-9 are found stored within the specific granules of the neutrophil, whereas most other MMPs are produced by different connective tissue cells after stimulation with a variety of mediators.

MMPs are divided into four main groups called the stromelysins, collagenases, gelatinases and MT-MMPs.⁹ The stromelysins have broad substrate specificity, and the natural substrates of these enzymes are probably proteoglycans, fibronectin and laminin.¹⁰ Stromelysin-1 (MMP-3) is not normally widely expressed but can readily be induced by growth factors and cytokines such as interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α). The three stromelysins have similar substrate specificity but their expression patterns are often quite distinct.

There are three mammalian collagenases: MMP-1, MMP-8, and MMP-13. These enzymes, once activated, cleave fibrillar collagens at a single site to produce fragments three fourths and one fourth the original size. The enzymes differ in their specificity for different collagens, with MMP-13 having much broader substrate specificity than the other collagenases. Both MMP-1 and MMP-13 are synthesized by macrophages, fibroblasts, and chondrocytes when these cells are stimulated by inflammatory mediators. MMP-8 is predominantly released from neutrophils on stimulation of the cell, but this MMP can also be produced by chondrocytes, and all three collagenases are present in diseased cartilage (Fig. 20.2). MMP-13 is often controlled in a different way from MMP-1; retinoic acid, which downregulates MMP-1, is known to upregulate MMP-13 in some cell types.

The two gelatinases cleave denatured collagens, type IV and V collagen, and elastin. Expression of MMP-2 is the most widespread of all the MMPs; MMP-9 is expressed in a wide variety of transformed and tumor-derived cells. Both MMP-2 and MT1-MMP (MMP-14) have also been shown to have collagenolytic activity, and the cell-surface location of MT1-MMP ideally situates it for the pericellular proteolysis that is often evident in cartilage affected by OA.

Levels of different MMPs are increased in rheumatoid synovial fluid, in conditioned culture media from rheumatoid synovial tissues and cells, in synovial tissue at the cartilage-pannus junction in rheumatoid joints, in cartilage with OA, and in animal models of arthritis.^{11,12} These proteinases are implicated in the pathologic destruction of joint tissue and are involved in the normal turnover of connective tissue matrix that occurs during growth and development. In OA, rates of both matrix synthesis and breakdown are increased, which leads to the formation of excess matrix in some regions (osteophytes) with focal lesions (loss of matrix) in other areas.

The MMPs therefore need careful control,¹⁰ which occurs at a number of critical steps (Fig. 20.3); these include synthesis and secretion, activation of the proenzymes, and inhibition of the active enzymes.

Synthesis and secretion

IL-1, TNF- α , and IL-17 stimulate numerous cell types to produce proinflammatory and degradative molecules. The synthesis and secretion of MMP-1, MMP-3, and other MMPs are stimulated by such mediators.¹³

Fig. 20.2 Cell-cell interactions between T cells, synovial fibroblasts, and macrophages within the pannus tissue give rise to a mixture of cytokines and growth factors that act on these cells and on chondrocytes to increase procollagenase-1 (matrix metalloproteinase-1 [MMP-1]), procollagenase-2 (MMP-8), procollagenase-3 (MMP-13), or membrane type 1 (MT1)-MMP (MMP-14). After activation, if local levels exceed the available tissue inhibitor of metalloproteinases (TIMPs), collagen destruction ensues. MMP-14, located at the cell surface, can initiate activation cascades, as can serine proteinases that activate the procollagenases. Within the joint cavity, neutrophils can also release collagenase-2 (MMP-8), gelatinase B (MMP-9), or elastase at or close to the cartilage surface where degradation will occur unless α_2 -macroglobulin (α_2 M) or TIMPs bind and inactivate the enzymes.

Fig. 20.3 (a) The matrix metalloproteinases (MMPs) are controlled by mechanisms that include upregulation by combinations of cytokines and growth factors, activation of the secreted enzymes, and inhibition by tissue inhibitors of metalloproteinases (TIMPs). (b) Other factors often alter the cellular response to these stimuli, and different cells can respond to growth factors and cytokines in a number of ways.

Arthritic joints have large numbers of different cell types that produce specific cytokines and growth factors that often differ in their action on individual cell types (see Fig. 20.3b). It is also likely that multiple cytokines will be present within such an inflammatory milieu, thus making it difficult to predict the outcome of blocking the action of an individual cytokine to prevent tissue destruction. TNF- α blockade in some patients with rheumatoid arthritis (RA) successfully reduces inflammation and joint destruction, whereas some studies suggest that blocking other cytokines such as IL-6, IL-17, or oncostatin M (OSM) may confer similar benefit, especially in patients unresponsive to a given biologic agent. Cytokines and growth factors mediate their effects on cells by binding to specific cell-surface receptors. A “signal” is transduced to the nucleus via specific intracellular signal transduction pathways that culminate in the activation or repression of target genes. Signaling in inflammation is complex, and multiple signaling cascades are often activated by a given cytokine in different cell types. A further level of complexity is that interactions, or “crosstalk,” between different signaling pathways can occur and mediate the gene expression of degradative molecules.¹⁰ The key components of signaling pathways are an attractive therapeutic target because they allow small molecules to be used as drugs, and specific inhibitors of the JAK/STAT pathway have been tested successfully in trials.^{14,15} Recent work has also suggested that metalloproteinases are regulated epigenetically, both at the transcriptional level (i.e., by promoter DNA methylation) and post-transcriptionally by microRNA.¹⁶

Activation of proenzymes

Activation of latent pro-MMPs is an important and understudied control point in connective tissue breakdown. The propeptide is removed proteolytically, which allows the enzyme to hydrolyze peptide bonds, and activation is likely to be achieved in a tightly controlled environment close to the cell surface. Active MMP-3 activates procollagenases and other MMPs. Recent data implicate MT1-MMP, which itself is activated by the serine proteinase furin, as an important initiator of MMP activation cascades. Plasmin, matriptase, and other serine proteinases activate some members of the MMP family (see later), and *in vitro* studies have demonstrated that inhibitors of furin, matriptase, and plasmin can block cartilage breakdown.¹⁷

Inhibition of active enzymes

All active MMPs are inhibited by tissue inhibitors of metalloproteinases (TIMPs),¹⁸ which are highly stable proteins that bind tightly to active MMPs in a 1:1 ratio. TIMPs play an important role in controlling connective tissue breakdown by blocking activated MMPs (see Figs. 20.2 and 20.3). If TIMP levels exceed those of active enzymes, connective tissue turnover is prevented. TIMP-3 is bound by the extracellular matrix after secretion and also inhibits members of the ADAM (a disintegrin and metalloproteinase) and ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) families (see the next section). TIMP-4 is predominantly localized in heart tissue but can be produced by joint tissues. TIMP-1 and TIMP-3 are upregulated by growth factors such as transforming growth factor- β (TGF- β), insulin-like growth factor 1 (IGF-1), and OSM; these agents also upregulate matrix synthesis. The mechanisms that control the extracellular activity of the MMPs are illustrated in Figure 20.3.

ADAM and ADAMTS proteinase families

Two additional families of proteinases, both closely related to MMPs, are also implicated in cartilage biology, particularly in relation to proteoglycan turnover. ADAMs are usually membrane-anchored proteinases with diverse functions conferred by the addition of different protein domains. The disintegrin domain can bind to integrins and prevent cell-cell interactions; cysteine-rich, epithelial growth factor (EGF)-like, transmembrane, and cytoplasmic tail domains are also found. Some members are associated with the cleavage and release of cell-surface proteins. For example, ADAM-17 is known for its ability to release TNF- α from the cell surface. Other ADAMs have also been described in cartilage, including ADAM-10, ADAM-12, and ADAM-15.

ADAMTS family members are distinguished from the ADAMs in that they lack these latter three domains but have additional thrombospondin-like domains (which can number up to 13 and are located predominantly at the C-terminus); they are thought to mediate interactions with the extracellular matrix.¹⁹ Some ADAMTS proteinases can, under certain circumstances, be produced as alternatively spliced forms that differ primarily in the number of their thrombospondin repeats and may give rise to differences

Fig. 20.4 (a) Structure of aggrecan. The major proteoglycan in human cartilage is aggrecan, a protein with three globular domains: G1 to G3. Between G2 and G3 there is a linear region of polypeptide to which charged sugars are attached that attract water and cause the aggrecan to swell. (b) Proteinases that cleave the interglobular domain. Both ADAMTS-4 and ADAMTS-5 and matrix metalloproteinases (MMPs) can cleave aggrecan at specific amino acid sequences between the G1 and G2 domains. Cleavage in this region by ADAMTS-4 and ADAMTS-5 is thought to be key to the pathologic loss of aggrecan from cartilage. (c) Cleavage of aggrecan by aggrecanases and MMPs. ADAMTS-4 and ADAMTS-5 are metalloproteinases that belong to the ADAMTS family. They are either associated with the chondrocyte membrane or released into the extracellular space where aggrecan is cleaved between the G1 and G2 domains, as well as at several sites close to the G3 domain. A specific neoepitope is released and is found in diseased synovial fluids. The G1 domain, which is bound to hyaluronic acid, can be subsequently cleaved by MMPs, with a specific MMP neoepitope being left that can be detected in arthritic cartilage in late-stage disease. TIMP-3 inhibits the release of aggrecan.

in their substrate specificity and localization within the extracellular matrix. Several members of this family are recognized as aggrecanases,¹⁹ and some of these enzymes, most notably ADAMTS-4 and ADAMTS-5,²⁰ are thought to be responsible for the cleavage of cartilage proteoglycan (Fig. 20.4). Recent studies suggest that an enzyme is present on the surface of chondrocytes that also cleaves aggrecan and is distinct from ADAMTS-4 or ADAMTS-5; however, it remains unclear whether it is an ADAMTS family member that is attached tightly via thrombospondin domains or whether a separate

enzyme is present. Interestingly, many of the ADAM and ADAMTS family members are inhibited by TIMP-3, which in *in vitro* studies, effectively blocks release of aggrecan from cartilage.

Serine proteinases

There are almost as many serine proteinases (31%) in the human degradome as there are metalloproteinases (34%),⁵ which makes this proteinase class

Fig. 20.5 Many growth factors (e.g., transforming growth factor-β [TGF-β], interferon-γ [IFN-γ], insulin-like growth factor 1 [IGF-1], interleukin-4 [IL-4], IL-13) increase the synthesis of collagen, increase proteinase inhibitors, and often reduce the production of proteinases. IL-1 and tumor necrosis factor-α (TNF-α) increase the production of proteinases and can reduce collagen synthesis. Other agents, such as oncostatin M (OSM), IL-17, basic fibroblast growth factor (bFGF), and platelet-derived growth factor (PDGF), can further influence these processes. TIMP, tissue inhibitor of metalloproteinase.

increasingly interesting in terms of joint destruction. Indeed, both direct and indirect roles for serine proteinases have been described, including regulation of cell signaling and modulation of the biologic activity of growth factors; these events can significantly alter inflammatory responses.¹⁷ The complement serine proteinase C1s can degrade IGF-binding protein-5 (IGFBP-5) to release active IGF-1, a growth factor integral in controlling cartilage damage. Complement activation components are elevated in the synovial fluid, synovium, and cartilage of patients with arthritis, and targeted deletion or inhibition reduces disease severity in murine arthritis models.²¹ Interactions between TNF-α and the complement system may contribute to disease pathogenesis, and therapeutics that target complement components are now being developed for the treatment of RA.²² As well as a pro-MMP activator, plasmin can activate TGF-β, release IGF-1 from IGFBPs and activate the complement cascade. The serine proteinases neutrophil elastase and cathepsin G are stored in azurophil granules and released after exposure of the neutrophil to inflammatory stimuli. In mice deficient in both neutrophil elastase and cathepsin G, experimental arthritis is less severe with reduced inflammatory cell infiltration, thus suggesting that these neutrophil serine proteinases are important in promoting the inflammatory process by establishing chemotactic gradients that recruit immune cells and enhance inflammation. Modulation of the biologic activity of chemokines is another important role,¹⁷ and it is now apparent that serine proteinase activators of protease-activated receptor-2 (PAR-2), such as mast cell β-tryptase and chondrocyte matriptase, contribute to joint swelling and synovial vasodilatation, as well as MMP expression and activation.^{23–25} Moreover, the protective phenotype of PAR-2-deficient mice in experimental RA and OA^{24,26} strongly suggests these proteolytic activators could be therapeutic targets. Conversely, some serine proteinases are thought to be protective, such as fibroblast activation protein-α (FAP-α) and dipeptidyl peptidase IV (DPPIV). These transmembrane enzymes have unusual catalytic activity in that they hydrolyze postproline bonds two or more residues from the N-terminus of target substrates, which makes them important regulators of biologically active peptides/neuropeptides and chemokines. Inhibition of FAP-α and DPPIV increases cartilage invasion by RA synovial fibroblasts²⁷ and, because FAP-α is elevated during inflammation as well as in OA cartilage, and α₂-antiplasmin is a physiologic substrate of FAP-α, these findings suggest an important protective feedback mechanism for these enzymes in maintaining cartilage homeostasis.

INTRACELLULAR PATHWAYS—ACID PROTEINASES

Levels of cathepsin D (an aspartic proteinase) and cathepsin B (cysteine proteinase) are increased in OA cartilage and increased levels of cathepsins

B, H, and L (cysteine proteinases) are reported in antigen-induced rat arthritis models and within rheumatoid joints.²⁸ Incubation of resorbing cartilage with specific cathepsin B inhibitors blocked the release of proteoglycan fragments, an action suggesting the involvement of an intracellular route for cartilage proteoglycan breakdown. Cathepsin K can also cleave collagen, albeit at a different site from the MMPs, and the presence of chondroitin sulfate increases the activity and stability of this enzyme. A correlation of cathepsin K-generated collagen fragments with increasing age in OA cartilage has been reported.²⁹ Cathepsin K is now a drug target for the treatment of osteoporosis in which bone resorption is excessive (see later). The relative contribution of intracellular and extracellular pathways to collagen breakdown is controversial. Tissues with high matrix turnover (e.g., periodontal ligament) or that have been stimulated to resorb have increased numbers of collagen-containing vacuoles, which suggests that these vacuoles are linked to resorption. Some work suggests that the intracellular pathway predominates in normal turnover whereas the extracellular route is prevalent only in pathologic conditions.³⁰ Close apposition of the intracellular and extracellular pathways will be found in many situations characterized by connective tissue turnover (Fig. 20.5).

OSTEOCLASTIC BONE RESORPTION

Bone is also destroyed in RA,³¹ and both the MMPs and cysteine proteinases are involved.³² For details see Chapter 22 and the online supplement.

MODEL SYSTEMS OF CARTILAGE BREAKDOWN

A large number of *in vitro* and *in vivo* models are used to study the mechanisms of joint destruction. Initiation of cartilage breakdown can be induced with IL-1, TNF-α, IL-17, retinoic acid, or other proinflammatory cytokine combinations in model systems.³⁶ Specific proteoglycan fragments are released first from resorbing cartilage (see Fig. 20.4). TIMP-3 blocks such release of proteoglycans, thus supporting a role for ADAMTS enzymes, particularly ADAMTS-5, and possibly other chondrocyte membrane metalloproteinases. Cysteine proteinase inhibitors can also block the release of proteoglycans from cartilage, thus indicating that they could be involved in upstream activation pathways.³⁷

The loss of collagen from cartilage is viewed as the final phase of tissue destruction and is essentially irreversible; attempts at repair do not lead to restoration of normal cartilage. Before the loss of collagen, many of the minor components of the extracellular matrix are first degraded, including molecules that are closely associated with the collagen fibrils, such as cartilage oligomeric matrix protein (COMP), decorin and type IX collagen. It

Osteoblasts respond to parathyroid hormone and other agents that induce bone resorption, such as IL-1 and TNF- α , by increasing the secretion of MMPs to remove the osteoid layer on the bone's surface. Osteoclast precursors then adhere to the exposed bone surface, differentiate, and form a low-pH microenvironment beneath their lower surface. This removes mineral, and lysosomal proteinases then resorb the exposed matrix (Fig. e20.1). Cathepsins B and L cleave collagen types II, IX, and XI and destroy cross-linked collagen matrix at low pH. Osteoclasts produce cathepsin K, which cleaves type I collagen at the N-terminal end of the triple helix. This enzyme plays a key role in the degradation of bone collagen and its expression correlates with bone resorption. It is also produced by synovial fibroblasts and is thought to contribute to synovium-initiated bone destruction in the rheumatoid joint.³³ Bone resorption is impaired in situations in which cathepsin K is deficient, evidence that has made cathepsin K a drug target for the treatment of osteoporosis in which bone resorption is excessive.

There is clear evidence for a central role of receptor activator of nuclear factor- κ B ligand (RANKL) in the bone destruction seen in RA. This member of the TNF ligand family of cytokines is abundantly produced by T cells and synovial fibroblasts in RA synovial membrane and it stimulates the formation of multinucleated osteoclasts. It is upregulated by a variety of cytokines, including IL-1, TNF- α , IL-11, OSM, parathyroid hormone-related peptide (PTHrP), macrophage colony-stimulating factor (M-CSF) and IL-17. It binds to a specific receptor, RANK on the surface of osteoclast precursors. Increased levels of RANK and RANKL, as well as multinucleated cells, are evident in arthritis models associated with bone erosions. The potent activity of IL-17 in osteoclastogenesis is mediated by the upregulation of RANKL and its action is antagonized by the decoy receptor osteoprotegerin (OPG). OPG is effective in blocking bone resorption³¹ and in rat adjuvant-induced arthritis and the arthritis of TNF transgenic mice³⁴; it protects against the development of bone and cartilage destruction. Studies have investigated the use of antisclerostin antibodies as a treatment to prevent osteoporotic bone loss because reduced sclerostin levels are associated with high bone mass.³⁵

Fig. e20.1 Hematopoietic stem cells are induced to differentiate into osteoclast precursors by systemic hormones such as parathyroid hormone (PTH), as well as vitamin D₃; various cytokines and growth factors have stimulatory or inhibitory effects on this differentiation. These precursors mature into osteoclasts, which first remove the mineral component of bone via acidification of an extracellular zone on the bone surface and then mediate the breakdown of protein components through the production of matrix metalloproteinases (MMPs) and cathepsin K (catK); calcitonin inhibits osteoclast function. Osteoblasts are derived from reconstituting bone marrow cells that differentiate under certain stimuli into osteoblast precursors, which then further differentiate into mature osteoblasts. These cells model and repair bone by producing new mineralized bone matrix. Pathways that promote differentiation are in blue; pathways that inhibit it are in red. EGF, epidermal growth factor; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IGF, insulin-like growth factor; IL-1, interleukin-1; M-CSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; PDGF, platelet-derived growth factor; PTHrP, parathyroid hormone-related peptide; RANKL, receptor activator of nuclear factor- κ B ligand; TGF- β , transforming growth factor- β ; TNF- α , tumor necrosis factor- α .

is not known whether this disassembly of the matrix occurs in a defined sequence, but it is evident that a matrix as complex as articular cartilage requires numerous proteolytic activities to effect complete tissue destruction. Although IL-1 and TNF- α are sometimes able to initiate cartilage collagen resorption alone, when these cytokines are combined with OSM, rapid and reproducible release of collagen is found in bovine and porcine cartilage. Synthetic MMP inhibitors and TIMP-1 are able to prevent this release,³⁶ a finding that strongly implicates the collagenolytic MMPs in this process.

Murine models of RA include collagen-induced arthritis. Implantation of RA synovial fibroblasts with normal articular cartilage under the renal capsule of mice with severe combined immunodeficiency leads to maintenance of the aggressive phenotype of the synovial fibroblasts that invade the cartilage, whereas OA synovium does not.³⁸ Adenoviral delivery of proinflammatory cytokines intraarticularly can also lead to RA-like tissue destruction with concomitant synovial hyperplasia.³⁹ These models emphasize the role that synovial fibroblasts play in destroying both bone and cartilage in RA, and methods have also been developed in which synovium and cartilage can be cocultured *in vitro*. The interplay between cartilage, bone, and synovium and the different points at which joint destruction can be blocked are illustrated in Figure 20.6. A role of inflammation and factors such as IL-1 in the progression of OA is now proposed. Although spontaneous OA animal models are available, surgical instability models are most

common in laboratory animals, including dog, guinea pig, rabbit, rat, mouse, sheep and goat.⁴⁰ Advantages of surgical models over spontaneous models include a significantly faster onset of disease with a decrease in both variability and dependence of genetic background.⁴¹ The two most common models are generated via either anterior cruciate ligament transection or destabilization of the medial meniscus (DMM), with DMM being the model of choice in the mouse.⁴¹ These models in the mouse have allowed the use of transgenic knockout (KO) or knock-in (KI) animals to provide insight into the mechanisms that regulate OA pathology.^{6,42} Despite these developments, no single model fully replicates human disease and it is unclear how well any of these models resemble idiopathic OA in the older human population.^{6,40}

METALLOPROTEINASE-DEFICIENT MICE IN MODELS OF DISEASE

Targeted gene disruption or KO experiments in mice have allowed investigation of the contribution of individual MMPs to many physiologic and pathologic processes, including arthritis.⁴³ All MMP KO mice are embryonically viable, but the MMP-9 KO exhibits an abnormal pattern of skeletal development, the MMP-20 KO shows severe abnormalities in tooth development, and the MMP-14 KO displays severe defects in skeletal development and dies within 3 to 16 weeks of age.

MMP-9 KO mice show developmental abnormalities that involve growth plate and endochondral ossification. Hypertrophic chondrocytes develop normally but apoptosis, vascularization, and ossification are delayed. MMP-9 appears to be important in the invasive activity of osteoclasts at resorption sites and mice deficient in MMP-9 exhibit a delay in osteoclast recruitment, although osteoclastic resorption of mineralized matrix still occurs.

MT1-MMP KO causes severe defects in both endochondral and intramembranous bone formation and gives rise to severe connective tissue defects and the development of arthritis. Bone marrow stromal cells from MT1-MMP KO mice show decreased bone formation, thus suggesting that MT1-MMP may influence the differentiation and activity of osteoblasts. MT1-MMP KO mice also have increased numbers of osteoclasts, thus suggesting that MT1-MMP may influence the differentiation and recruitment of these cells.

MMP-13 KO mice show only transient abnormalities in cartilage resorption during long-bone growth and fracture healing; however, when subjected to a surgical model of OA (DMM), cartilage erosion is inhibited in these mice even in the presence of aggrecan depletion, which supports the potential for therapeutic intervention in established OA with MMP-13 inhibitors. Furthermore, MMP-13 expression correlates with elevated hypertrophy-associated genes. The recapitulation of growth plate-like hypertrophic differentiation of chondrocytes has suggested an important role in the pathogenesis of OA. However, in the MMP-13 KO DMM animals, hypertrophy markers were still detected in cartilage that did not erode, which suggests that it is not the hypertrophic differentiation of chondrocytes *per se* that results in degradation of cartilage but rather the hypertrophy-associated expression of MMP-13. Of further interest was the observation that osteophytes still formed in the MMP-1 KO mice subjected to DMM, thus suggesting that osteophyte formation is not linked to articular cartilage destruction but to other factors, potentially joint instability.⁴⁴

In the development of antibody-induced arthritis (AbIA), an animal model of RA, MMP-2 KO mice showed significantly exacerbated arthritis in comparison to wild-type mice. Recovery from AbIA could be achieved in the MMP-2 KO mice by injection of wild-type fibroblasts. This suggests a suppressive role for MMP-2 in the progression of AbIA even though MMP-2 is overproduced in the AbIA joint in wild-type mice. In contrast to MMP-2 KO mice, MMP-9 KO mice show reduced levels of AbIA, an observation indicating that MMP-9 enhances arthritis in this model. The double-KO mice showed no significant difference from the wild-type mice, probably reflecting the net effects of both exacerbated arthritis by MMP-2 deficiency and reduced arthritis by MMP-9 deficiency. In cartilage with AbIA, erosion was mild even in severely arthritic mice; therefore the roles of MMP-2 and MMP-9 in cartilage erosion could not be determined. Somewhat counterintuitively, however, in DMM-induced OA, MMP-9 disruption resulted in more severe OA.

Disruption of the MMP-3 gene has been investigated in several models of arthritis: antigen-induced arthritis (AIA), collagen-induced arthritis (CIA), and induction of OA by both a collagenase-induced instability model of OA⁴⁵ and surgical transection of the medial collateral ligament and partial medial meniscectomy. All studies show no significant differences in either inflammation or proteoglycan depletion between the MMP-3 KO mice and controls. The major MMP cleavage site in aggrecan generates

Fig. 20.6 Therapeutic intervention points for preventing connective tissue destruction and cellular mechanisms involved in tissue damage. The destructive cycle of events can be broken in a number of ways, including (a) (1) blocking the entry of harmful cells, (2) removal of harmful cells from the joint, (b and c) (3) blocking or mimicking cytokine or growth factor action, (4) blocking the intracellular signaling pathways involved in the production of proteinases, (5) preventing the activation of proteinases, and (6) direct inhibition of the destructive proteinases degrading bone or cartilage. (c) Within the joint, mixtures of cytokines stimulate chondrocytes to release and activate enzymes that damage the cartilage matrix. Within the synovium, fibroblasts, macrophages, and T cells interact to produce tissue damage in bone and cartilage. The cytokines released also activate osteoclasts, which leads to the destruction of bone.

the C-terminal neopeptide VDIPEN. In the AIA model and in collagenase-induced instability models, VDIPEN staining was eliminated or significantly reduced in MMP-3 KO mice but in CIA and meniscectomized mice, VDIPEN staining was the same as in wild-type mice. MMP-mediated aggrecan cleavage has been further assessed via a KI mouse in which the wild-type cleavage site was altered so that it was impervious to MMP activity. These mice have no developmental problems, which implies that MMP-mediated aggrecanolysis is not important in growth plate remodeling. In addition, lack of a growth plate phenotype in KOs for ADAMTS-1, ADAMTS-4, or ADAMTS-5, as well as a KI engineered to resist aggrecanase-mediated aggrecanolysis (the N-terminal ARGSV neopeptide), supports nonproteolytic mechanisms of aggrecan remodeling in the growth plate.⁴⁶ The ADAMTS-4 and ADAMTS-5 KO mice have revealed that ADAMTS-5, at least in mice, plays a major part in tissue turnover in models of OA and inflammatory arthritis.^{20,47}

The COL2-3/4C neopeptide (generated by collagenases) was used to detect collagen cleavage, and this was eliminated in the AIA model in MMP-3 KO mice versus wild-type controls but was unchanged in the meniscectomized model. In the AIA model, MMP-3 appears to have an important role in the mechanisms leading to cleavage of type II collagen. In contrast, the meniscectomized MMP-3 KO mice exhibited accelerated formation of OA lesions when compared with wild-type mice. These results could suggest that MMP-3 plays an important role in homeostasis in healthy cartilage by balancing anabolism and catabolism of the cartilage matrix or, alternatively, that the MMP-3 gene is compensated by another similar gene such as MMP-10.

Mice deficient in either TIMP-1 or TIMP-2 exhibit no major phenotype, whereas a mild but transient OA with increased proteoglycan loss and increased generation of the VDIPEN neopeptide develops in TIMP-3 KO mice. As TIMP-3 KO mice age, there is evidence of increased cartilage catabolism; lack of TIMP-3 will lead to an altered metalloproteinase/TIMP balance and the higher levels of TNF- α could also be due to lack of inhibition of the metalloproteinase TNF- α -converting enzyme (TACE).⁴⁸

Studies in KO mice are therefore a powerful approach for defining protein function and application of these KO experiments in mouse models of diseases has shown that MMPs serve specific roles in a variety of pathologic processes. These data need to be interpreted carefully because of significant differences between mice and humans in MMP expression (e.g., MMP-1), gene redundancy, and the distribution of load across joints. However, novel targets for therapeutic intervention can be investigated by using these models.

THERAPEUTIC INHIBITION OF PROTEINASES

The use of synthetic proteinase inhibitors as drugs to prevent joint destruction in the arthritides has been unsuccessful to date. Compounds that inhibit MMPs are the most studied¹⁰ with the aim of treatment being to shift the balance away from matrix degradation to prevent the loss of connective tissue matrix without leading to excess synthesis. Initial problems with the oral availability of MMP inhibitors have been overcome. Despite favorable results in the treatment of some cancers, trials of compounds that inhibit the collagenases in patients with RA have not been successful. It may be that the compounds used were unsuitable or that collagenases are not the best target. It is not known whether sufficient penetration of cartilage by these compounds was achieved or whether their specificity was altered during absorption.

The antibiotic doxycycline and derivatives with no antibiotic activity weakly inhibit MMPs, and these compounds have been licensed for the treatment of periodontal disease. They are also effective in animal models of arthritis and have therefore been proposed as a treatment to prevent cartilage damage. In a randomized placebo-controlled trial of overweight women with unilateral radiographic knee OA, those randomized to doxycycline 100 mg twice daily had a 33% reduction in the mean amount of joint space narrowing over a period of 30 months.⁴⁹ It is possible that specific TIMPs could be used successfully in the future to halt the progressive and chronic destruction of connective tissue seen in the arthritides. It may be necessary to combine different proteinase inhibitors, either in sequence or with other agents that target different but specific steps in the pathogenesis, before the chronic cycle of joint destruction found in these diseases can be broken (see Fig. 20.6).

Recent interest has begun to focus on compounds that target events before the induction of these destructive genes. Some compounds that block specific signal transduction pathways have been shown to prevent cartilage destruction *in vitro* and compounds are in development that specifically inhibit the Janus kinases as an oral disease-modifying therapy.⁵⁰

REPAIR OF CONNECTIVE TISSUE MATRIX

Cartilage metabolism may be altered by effects on cellular proliferation, migration or differentiation and the control of individual genes (see Fig. 20.3b). The effect of any particular growth factor also depends on the differentiation state of the cell. Various types of cells in tissues may respond differently to particular cytokines and growth factors. Other local conditions will affect these responses, such as mechanical loading, oxygen tension, and the presence of other factors (see Fig. 20.3b).

Diseased joints have areas of cartilage in which new matrix synthesis occurs, as well as net loss of the extracellular matrix. Growth factors play major roles in regulating normal matrix synthesis and in the processes that protect cartilage in disease. Growth factors such as TGF- β and bone morphogenic proteins (BMPs) have direct effects on chondrocytes and are known to be involved in matrix deposition in OA (e.g., osteophyte generation).⁵¹ However, TGF- β is also known to induce MMP-13 expression under some circumstances, and lack of TGF- β responsiveness with increasing age may be an important caveat for effective tissue repair in disease. Other factors, such as hormones, corticosteroids, prostaglandins, peptides or retinoids, may also influence cellular responses to these growth factors.

TGF- β and IGF-1 have profound effects on the synthesis of matrix components by chondrocytes.⁵² TGF- β can downregulate the production of several matrix-degrading proteinases and upregulate proteinase inhibitors such as TIMP-1 or plasminogen activator inhibitor, thus suggesting that it may prevent cartilage destruction by both stimulating synthesis and blocking degradative pathways. TGF- β is locally synthesized by chondrocytes, affects protein synthesis, and potentiates the stimulation of DNA synthesis achieved with other growth factors rather than initiating this itself. IGF-1 mimics many of the actions of TGF- β and has a significant effect on matrix synthesis but does not have the same mitogenic properties or affect protein synthesis to the same extent. Within cartilage, TGF- β and IGF-1 are stored in considerable quantities bound to different matrix components. More recently, connective tissue growth factors and members of the BMP family have been shown to have anabolic effects on cartilage and bone. The source of growth factors will vary. They can be produced by cells outside the cartilage and diffuse in, or they can be produced locally by chondrocytes. The control mechanisms are complex and growth factors also exist in a latent form; other proteins, such as IGFBPs, may be present that sequester the factors and prevent them from binding to cellular receptors. The activity of some MMPs can cause the release of growth factors as matrix is degraded. This provides positive feedback mechanisms that redress the balance between degradation and synthesis of matrix components.

Growth factors are recognized as being protective of cartilage, stimulating matrix synthesis, and blocking the effects of proinflammatory cytokines. Other factors also protect joint tissues. Interferon- γ inhibits cytokine-stimulated bone resorption and IL-1- or TNF- α -stimulated collagenase production by chondrocytes, as well as reduces IL-1-stimulated release of prostaglandin from cartilage. IL-4, IL-13 and IL-10 have all been shown to oppose the effects of these proinflammatory cytokines by blocking MMP secretion or activation or increasing inhibitor production and matrix synthesis. Platelet-derived growth factor (PDGF) and basic fibroblast growth factor (bFGF) can also affect cartilage homeostasis by inducing cells to migrate, differentiate or proliferate. In addition, bFGF stimulates the production of plasminogen activator inhibitors and TIMP-1 in fibroblasts and endothelial cells. All these growth factors are likely to stimulate cartilage repair, and many do not act alone but rather synergistically to promote the synthesis of new matrix.

MODELS OF MATRIX REPAIR

Considerable progress has been made in cartilage repair. Defects found in diseased or damaged cartilage can be repaired in model systems after the delivery of agents that will stimulate chondrocytes to synthesize new matrix.⁵³ Different approaches have been used, including the following:

- Isolation of autologous chondrocytes or stem cells, which are grown and differentiated in culture and then implanted into defects at high density
- Grafting of cartilage into large defects
- Filling of defects with various natural or synthetic polymers
- Addition of growth factors to encourage migration into the defect and subsequent synthesis of matrix components

Defects in cartilage have been filled with biodegradable matrices that contain low concentrations of a chemotactic or mitogenic factor that is

slowly released, such as TGF- β . Many growth factors have been shown to be effective including bFGF, PDGF, EGF, growth hormone, TGF- β and IGF-1. A cartilage-like matrix is produced within defects after 6 weeks. Successful induction of cartilage is now being achieved in experimental models and could be adapted for clinical use to allow intervention in the disease process. A key issue here is the “quality” of the cartilage matrix generated, and there is an emphasis on ensuring an appropriate ratio of types I and II collagen, where type II should predominate. The potential use of mesenchymal stem cells (nonhematopoietic progenitor cells found in various adult tissues) for tissue engineering to generate replacement tissues for repair of joint damage in arthritis is an attractive area of research,⁵⁴ but

it will still be some time before such stem cell therapies are used clinically. However, successful integration of such matrices with host tissue is often problematic, although advances in regenerative medicine, especially in the area of nanotechnology, have led to novel surface scaffolds for implants that provide specific biofunctionality to better encourage biointegration of implants.⁵⁵

These techniques remain limited because they rely on surgical intervention, which may be practical only in large joints. However, when traumatic injury has resulted in damage to cartilage or when large joints have a discrete and well-defined injury, this procedure may benefit patients by increasing the chance of cartilage repair.

Principles of tissue engineering and cell- and gene-based therapy

■ ULRICH NÖTH ■ LARS RACKWITZ ■ ANDRE F. STEINERT ■ ROCKY S. TUAN

- Tissue engineering is an interdisciplinary research approach that combines the principles and methods of engineering sciences, cell and molecular biology, and clinical medicine with the aim of replacing injured or degenerated human tissues.
- The central dogma of tissue engineering states that a target tissue-specific template for replacing injured tissue relies on three principal components: cells, cell carriers (scaffolds), and external stimuli (e.g., growth factors or mechanobiologic stimuli).
- Mesenchymal stem cells are the most promising cell candidate for musculoskeletal tissue engineering because they can easily be obtained from mesodermally derived tissues (i.e., bone marrow), possess high expansion capacity, are able to differentiate into a number of mesenchymal lineages, and exhibit immune suppressive effects.
- Innovative production methods (i.e., electrospinning) allow the fabrication of biomimetic, target tissue-specific three-dimensional templates build up from synthetic or natural polymers (or from both).
- Various gene products (i.e., interleukin-1 receptor antagonist [IL-1ra], IL-4, IL-10, nuclear factor κ B) have been identified as potential therapeutic agents for treating rheumatic disorders, whereas gene delivery can be realized via viral (transduction) and nonviral (transfection) gene therapy technologies.

INTRODUCTION

Tissue engineering and cell-based therapies are emerging disciplines that constitute the principal technologies in the relatively new field of regenerative medicine. These technologies are directed toward self-regeneration and involve the use of biomaterials or biologically active molecules, application of differentiated or undifferentiated cells, functional tissue engineering, organ transplantation, and process technologies, as well as the development of regulatory standards (Fig. 21.1). In orthopedic surgery, autologous chondrocyte implantation (ACI) has become an established technique for the repair of focal articular cartilage defects in young adults. On the other hand, repair of degenerated cartilage lesions arising from diseases such as osteoarthritis (OA) or rheumatoid arthritis (RA) remains one of the greatest orthopedic challenges. The key underlying cause of this challenge is the inflammatory environment that drives the competing anabolic and catabolic processes toward extensive joint and cell transplant degeneration. As a result of intensive research in the past 2 decades, adult mesenchymal stem cells (MSCs) have emerged as a promising candidate cell type for the treatment of rheumatic diseases, principally because of their well-characterized ability to differentiate along the chondrogenic pathway and their recently demonstrated antiinflammatory and immune suppressive properties through trophic mediators.

TISSUE ENGINEERING

Tissue engineering is an interdisciplinary research approach with the goal of replacing injured or degenerated human tissues to restore their form, structure, and function by combining the principles and methods of engineering sciences, cell and molecular biology, and clinical medicine.^{1,2} From its beginning in the early 1990s, “tissue engineering” has developed into its own scientific and clinical discipline, with potential application for almost every tissue of the human body. The central dogma of tissue engineering

states that a target tissue-specific template for replacing injured or degenerated tissue relies on three principal components: cells, cell carriers (scaffolds), and external stimuli (e.g., bioactive molecules, including growth factors and genes, or mechanobiologic stimuli) (Fig. 21.2).

In the context of tissue engineering, the basic function of the scaffold is to provide a temporary structure for the seeded cells or migrating host cells to adhere to and subsequently to synthesize new native extracellular matrix (ECM) in a shape and form guided by the scaffold. The main criteria for scaffold design include controlled biodegradability, suitable mechanical strength, and appropriate surface chemistry, as well as the ability to regulate cellular activities, such as proliferation, cell-cell and cell-matrix interactions, and directed differentiation.^{3,4} Scaffolds can be manufactured from native or synthetic polymers, with native materials exhibiting optimal biocompatibility and biodegradability and synthetic polymers having higher primary stability and being more accessible for macrostructure and microstructure formation. A key requirement for a tissue-engineering scaffold is optimal porosity to facilitate nutrition, proliferation, and migration of cells and to ensure cell colonization of the entire carrier. Although primary, tissue-specific cells (i.e., chondrocytes) are inherently the most suitable source of cells for cartilage tissue engineering, they have limitations in practice because of the shortage of supply, loss of phenotype during expansion culture, and potential donor site morbidity after harvest.^{3,5}

AUTOLOGOUS CHONDROCYTE IMPLANTATION

An established procedure for the treatment of symptomatic chondral or osteochondral defects of the knee joint guided by the principles of tissue engineering is the first generation of ACI, originally developed by Brittberg and coworkers⁶ 2 decades ago. First, a cartilage biopsy sample is taken arthroscopically from a small, non-load-bearing area. After enzymatic isolation and chondrocyte expansion in culture *in vitro*, a second surgical procedure is performed that involves exposure of the knee joint via arthrotomy, débridement of the cartilage defect, and suturing of a periosteal patch or collagen membrane over the defect to obtain a cavity in which the culture-expanded chondrocytes can be injected and secured by sealing with fibrin glue. This technique achieves predominantly good to very good long-term clinical results in more than 70% of patients,⁷ and the results are superior to those of sole débridement or osteochondral cylinder transplantation.⁸

However, ACI has several disadvantages that need to be addressed. The use of periosteum can result in transplant hypertrophy, calcification, and delamination,⁹ and the cell suspension has the potential to leak and thus compromise the development of sufficient neotissue at the defect site. Recent experimental and clinical research has been directed toward the development of matrix-associated procedures for ACI whereby biocompatible scaffolds are used as a vehicle for secure delivery of primary chondrocytes to the defect site. Today, clinical experience and promising clinical outcome data using collagen type I membranes or hydrogels,¹⁰ a copolymer of polyglycolic acid (PGA), polylactic acid (PLA), and polydioxanone, and hyaluronic acid have been reported.³ For example, use of a collagen type I hydrogel, which minimizes potential chondrocyte dedifferentiation, as seen in a monolayer, by providing a three-dimensional environment subsequent to enzymatic cell isolation, results in homogeneous cell distribution and promotes cartilage-specific cell differentiation and ECM deposition within the scaffold.¹¹

In contrast to the surgical treatment of focal articular cartilage lesions, which can result from acute injury or osteochondrosis dissecans, regenerative approaches to the treatment of OA or RA must take into consideration the fact that the cartilage damage arises from an underlying disease process. It is noteworthy that acute cartilage injury and osteochondrosis dissecans

Fig. 21.1 Principal technologies of regenerative medicine targeting the reconstruction of damaged or diseased human tissue and organ function. EMEA, European Medicines Agency; FDA, Food and Drug Administration.

Fig. 21.2 Functional components of the classic tissue engineering triad. BMPs, bone morphogenetic proteins; IGFs, insulin-like growth factors; TGFs, transforming growth factors; VEGF, vascular endothelial growth factor.

often take place in an otherwise healthy joint. The patient may be young, and thus a localized treatment may be sufficient to repair the focal defect. On the other hand, with OA and RA the patient is likely to be older and thus requires treatment of at least one compartment or the entire articulating surface. In addition, inflammatory conditions in the joint are likely to result in degradation of any engineered cartilage.¹² Consequently, unless the underlying disease is treated effectively and technologies are available to restore whole compartments, any cell-based treatment of OA and RA is unlikely to be of long-term benefit.

MESENCHYMAL STEM CELLS

The advantage of adult MSCs, which can potentially overcome the shortcomings of chondrocytes, is that they can easily be obtained from a bone marrow aspirate or other mesodermally derived tissues, possess high expansion capacity, and are able to differentiate into a number of

mesenchymal lineages.^{4,13} In particular, MSCs have been shown to undergo efficient chondrogenic differentiation *in vitro* and *in vivo*.^{4,14} MSCs are commonly isolated from a tissue-derived cell mixture by virtue of their avid adherence to cell culture plastic substrate or by density-gradient fractionation and are therefore intrinsically a heterogeneous cell population. Although no definitive MSC marker or markers have been identified, an immunophenotype positive for STRO-1, CD73, CD146, and CD106 and negative for CD11b, CD45, CD34, CD31, and CD117 has been shown to most reliably characterize the MSC population.^{4,13,14} For the purpose of cartilage regeneration, extensive analyses of microenvironments that promote chondrogenesis in MSCs *in vitro* have been performed. Conditioning the culture medium with growth factors such as fibroblast growth factor-2 or transforming growth factor- β (TGF- β) during monolayer expansion enhances positive selection for chondroprogenitor cells.¹⁵ The development of effective methods to maintain an articular cartilage phenotype without hypertrophy, ossification, or fibrinogenesis and a delivery system to localize the cells within a lesion without compromising their chondrogenic differentiation or the integrity of the repair tissue are additional requirements for the use of MSCs in articular cartilage regeneration.^{3-5,16}

Intraarticular injection of mesenchymal stem cells

Intraarticular injection of MSCs into the joint space is, at least conceptually, the simplest approach for their application to rheumatic diseases (Fig. 21.3a). Because the synovium lines all the internal surfaces of the joint space, except for cartilage and the meniscus, and is highly cellular, it is likely to be a primary tissue for interaction with MSCs.

Only few studies on direct intraarticular injection of MSCs into animal models of OA have been performed thus far. One study described the delivery of autologous MSCs via a dilute solution of sodium hyaluronan into the knee joints of a goat OA model induced by total medial meniscectomy and resection of the anterior cruciate ligament.¹⁷ The cell-treated joints showed evidence of marked regeneration of the medial meniscus, and implanted cells were detected in the newly formed tissue. Articular cartilage degeneration, osteophytic remodeling, and subchondral sclerosis were also reduced. Whether the changes observed in the MSC-treated joints resulted from repair tissue formation by the transplanted cells or the interaction of MSCs with host synovial fibroblasts at the site of injury remains unclear.

In another study, a freshly created partial-thickness cartilage defect in the knee joint of the mini-pig was treated by direct intraarticular injection of MSCs suspended in sodium hyaluronan.¹⁸ The results demonstrated that the cell-treated group showed improved cartilage healing in comparison to the control group without cells. The authors postulated that sodium hyaluronan might facilitate the migration and adherence of MSCs or MSC-like cells, probably derived from the synovium, to the defect. However, this repair tissue was of inferior quality, possibly because of insufficient MSCs localized to the site of injury, and it was shown to further deteriorate by 12 weeks.

Fig. 21.3 (a) Cell-based therapy for cartilage tissue engineering. Cells in suspension can be injected directly into the joint cavity, where they encounter all intraarticular tissues and might function via trophic mediators and exhibit chondroprotective or regenerative effects. Otherwise, cells (i.e., mesenchymal stem cells, chondrocytes) can be implanted in a matrix-guided manner into the cartilage defect after *ex vivo* conditioning with biochemical or biomechanical stimulation (or both). (b) Gene therapy approach for cartilage tissue engineering. Vectors can be directly injected in an intraarticular mode for *in vivo* gene delivery, or primary cells can be used as vehicles for *ex vivo* gene delivery. In the latter, successfully transduced cells can be applied to the joint cavity either by intraarticular injection as a suspension or by seeding within a matrix that can be implanted into a cartilage defect. Depending on which delivery approach is chosen, ubiquitous or local transgene expression is induced by the *ex vivo* genetically modified cells or by resident cells that are transduced via intraarticular vector application.

Matrix-guided application of mesenchymal stem cells

A more controlled method of cell application to restore the eroded cartilage surface is via a scaffold (see Fig. 21.3a). Seeding MSCs onto or into a scaffold, such as a biodegradable template, for proliferation and matrix production offers the advantage of providing an accessible, easy-to-manipulate, self-renewing source of otherwise spatially limited progenitor cells.

Synthetic scaffolds

Synthetic scaffolds offer the advantage of design manipulation, such as fiber diameter, pore size, degradation time, and reproducible fabrication. Many commonly studied synthetic scaffolds in cartilage repair are fabricated from α -hydroxy polyesters, including PGA, PLA, their copolymer poly(lactic-co-glycolic acid), and poly- ϵ -caprolactone.^{3,16,19,20} The topography and material properties of these scaffolds play an important role in their ability to support MSC differentiation; for example, a nanofibrous scaffold of biodegradable polymers demonstrates enhanced support of MSC proliferation and multilineage differentiation activities.^{20,21}

Natural scaffolds

In contrast to synthetic scaffolds, native biomaterials, including collagen type I, hyaluronic acid, chitosan, and alginate,^{3,22} offer the advantage of presenting a more natural microenvironment. These matrices are biodegradable, can be metabolized by cells via the action of endogenous collagenases,

elicit very limited if any inflammatory reaction, and offer a three-dimensional surrounding with material properties similar to those of hyaline cartilage. In particular, collagen gels may be formed to adapt to any desired defect shape. When compared with meshes or fleeces, in which cell seeding is often limited to mostly the superficial regions of the scaffold material, seeding in hydrogels permits even distribution of MSCs, thus promoting homogeneous ECM production.^{11,12}

The first clinical results of transplantation of MSCs seeded with collagen type I hydrogels for the repair of isolated full-thickness cartilage defects were reported by Wakitani and associates.²³ Two patients with patellar defects were treated with collagen gel–MSC constructs; the constructs were covered with a periosteal flap, and fibrocartilaginous filling of the defect was noted after 1 year, as well as significantly improved patient outcomes at 1-, 4-, and 5-year follow-up. In another case report from the same group,²⁴ a full-thickness cartilage defect in the weight-bearing area of the medial femoral condyle was treated. Histologically, the defect was filled with a hyaline-like type of cartilage tissue that stained positively with safranin O. One year after surgery, the clinical symptoms had improved significantly.

It is noteworthy that these pilot studies have been performed on isolated or focal articular cartilage defects in an otherwise healthy joint. A very different tissue microenvironment exists as a result of loss of joint homeostasis in OA and thus will influence MSC engraftment and differentiation.¹² The potential role and success of matrix-based cell transplantation in a joint diseased with RA are still unclear, as is the impact of the influence of this procedure on the development and progression of disease.²² In general, the

cartilage lesions in OA and RA are large, unconfined, and often opposed (“kissing lesion”) and affect more than one location. Thus, it is important to point out that current biologic and technologic developments are as yet inadequate to indicate sufficient retention of cell-loaded scaffolds in OA or RA lesions.¹²

Trophic and immune suppressive effects of mesenchymal stem cells

Even though the exact mechanisms that guide homing of the implanted or mobilized cells are not known, it is clear that MSCs themselves secrete a broad spectrum of bioactive molecules that have immunoregulatory^{25,26} or regenerative activities (or both).²⁷ The secreted bioactive factors have been shown to inhibit tissue scarring, suppress apoptosis, stimulate angiogenesis, and enhance mitosis of tissue-intrinsic stem or progenitor cells. Because of the complex, multifaceted secretory activity of MSCs, these cells have also been referred to as “medicinal signaling cells,” distinct from their differentiation capacity.²⁸

MSCs are potent modulators of the immune response and exhibit anti-proliferative capacity. They inhibit the proliferation of T lymphocytes induced by allogens, mitogens, or anti-CD3 and anti-CD28 antibodies. T-cell proliferation is inhibited by cell cycle arrest in the G0/G1 phase.²⁹ They also modulate the function of the major immune cell populations, including CD8+ cytotoxic T lymphocytes, B lymphocytes, and natural killer (NK) cells.³⁰ The immunosuppressive activity of MSCs is induced by a combination of inflammatory cytokines, including interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α), and interleukin-1 α (IL-1 α) or IL-1 β .³¹ In addition, MSCs exert significant effects on dendritic cell function by altering the generation and maturation of dendritic cells and skewing their function toward a regulatory phenotype.³² Two other key mechanisms are based on expression of the inducible nitric oxide synthase and indoleamine-2,3-dioxygenase enzymes.³³ Another important mediator of immunosuppression secreted by MSCs is HLA-G. HLA-G is a nonclassical HLA class I molecule that has been shown to suppress the proliferation of CD4+ T cells, induce apoptosis of CD8+ T cells, and inhibit NK cells.³⁴ MSCs can also modulate B-cell responses, depending on the ratio of both cell types. Indeed, at low ratios, MSCs inhibit the proliferation and activation of B cells, similar to their effect on T cells.³⁵

GENE TRANSFER STRATEGIES

The formation of tissues and elements of the skeletal system is the product of an exquisite biologic program that involves the regulated expression of genes and spatiotemporally specified activities of the gene products. Recent advances in cellular, molecular, and developmental biology have led to the identification of various gene products that might serve as therapeutic agents for treating rheumatic disorders, some of which are listed in Table 21.1.

Because exogenous DNA is not spontaneously taken up and expressed by cells in an efficient manner, genes have to be transferred to cells with the aid of vehicles or vectors. These can be assigned to two broad categories: those derived from viruses and those that are not. Viral gene delivery is known as transduction, and virus vectors being used in human clinical trials include retrovirus, adenovirus, adeno-associated virus (AAV), and herpes simplex virus. Overall, it can be stated that no good universal vector exists; instead, the choice of vector depends on the target application. Nonviral gene transfer is known as transfection and may be as simple as delivery of naked, plasmid DNA or via polymers or delivery by applying biophysical methods, such as electroporation. In general terms, nonviral vectors are less expensive, safer, and simpler than viral vectors, but they are considerably less efficient. Some of the specific advantages and disadvantages of each available vector system are listed in Table 21.2 and have been reviewed extensively elsewhere.³⁶ Of note in this context is the occurrence of insertional mutagenesis during human gene therapy trials, which has impeded further use of oncoretroviruses for nonlethal and nonmendelian diseases.³⁷

Regardless of the vector, genes may be transferred to their targets by *in vivo* or *ex vivo* strategies, the principles of which are illustrated in Figure 21.3.

Rheumatoid arthritis

The application of gene transfer to joints was pioneered by Evans and coworkers^{38,39} as a means of treating arthritic disorders. For the treatment

Gene products for cartilage restoration and protection in arthritic/rheumatic diseases

Therapeutic target	Gene product (examples)
Chondrogenic induction	Growth factors (e.g., TGF- β s, BMPs, Wnts) Signal transduction molecules (e.g., Smads) Transcription factors (e.g., SOXs, brachyury)
Osteogenic inhibition	Osteogenic inhibitors (e.g., noggin, chordin) Inhibitors of chondrocyte terminal differentiation (e.g., PTHrP, IHH, SHH, DHH) Signal transduction molecules (e.g., Smad6, Smad7, mIAP-1)
Inhibition of apoptosis	Caspase inhibitors (e.g., Bcl-2, Bcl-XL) FasL blockers (e.g., anti-FasL) NO-induced apoptosis inducers (e.g., Akt, PI-3-kinase) TNF- α , TRAIL inhibitors (e.g., NF- κ B)
Inhibition of senescence	Inhibitors of telomere erosion (e.g., hTERT) Free radical antagonists (e.g., NO antagonists, SOD)
Cartilage matrix synthesis	Growth factors (e.g., TGF- β s, BMPs, IGF-1) Extracellular matrix component (e.g., collagen type II) Enzymes for glycosaminoglycan synthesis (e.g., GlcAT-1)
Protection against inflammation	Cytokine antagonists (e.g., IL-1ra, sIL-1R, sTNFR, anti-TNF-Abs) Proteinase inhibitors (e.g., TIMP1, TIMP2) Antiinflammatory cytokines (e.g., IL-4, IL-10, IL-11, IL-13) Enzymes inhibiting IL-1 (e.g., GFAT)

TABLE 21.2

Vector systems for gene delivery applications for arthritic/rheumatic diseases

Vector	Characteristics
Nonviral	Overall weak efficiency, transient, many inflammatory
Adenovirus	High efficiency, transient, inflammatory
Adeno-associated virus	Moderate efficiency, safe, clinical trial for rheumatoid arthritis
Herpes simplex virus	High efficiency, cytotoxic, transient
Retrovirus	Long-term expression, clinical trial for rheumatoid arthritis, safety concern
Lentivirus	High efficiency, safety concern
Spumavirus	Moderate efficiency, no known disease in humans, not yet used in joints

of RA, biologic therapies that suppress the activities of proinflammatory cytokines such as TNF- α or IL-1 β have shown efficacy. However, such therapies are expensive and require repeated administration, only fewer than half of patients achieve a robust therapeutic response, and the issue of side effects remains of concern. Thus far, most attention has focused on local, intraarticular administration via *ex vivo* and *in vivo* modes of gene delivery (see Fig. 21.3). Genes encoding certain antiinflammatory cytokines such as IL-4, IL-10, and IL-13, antagonists of IL-1 and TNF, or antiangiogenic proteins have shown efficacy in several animal models of RA (see Table 21.1).⁴⁰⁻⁴³

Collectively, these studies have established a convincing proof of principle that has led to the development of human gene therapy protocols for the treatment of RA.⁴⁴ The first clinical protocol selected an IL-1 blocker, the IL-1 receptor antagonist (IL-1ra), as the transgene,³⁹ which was delivered in *ex vivo* fashion via a retrovirus to the metacarpophalangeal joints of nine individuals with severe RA. This phase 1 trial was completed successfully without incident, and the procedure was well tolerated by all nine patients included.³⁸ Another phase 1 protocol, largely similar to the protocol just mentioned, that included one patient has been completed in Düsseldorf, Germany,⁴⁵ with results comparable to those from the trial in Pittsburgh. A phase 1 trial of 15 individuals that involved direct, intraarticular injection of a recombinant AAV2 vector carrying cDNA encoding a fusion protein

consisting of two TNF soluble receptors (sTNFRs) combined on an immunoglobulin molecule was closed and converted into the first phase 2 clinical trial using the same vector.⁴⁴ It was temporarily halted by the U.S. Food and Drug Administration (FDA) because of the death of one individual enrolled in the study as a result of severe histoplasmosis.³⁷ However, the FDA determined that the vector was not responsible for the outcome and has allowed the trial to continue.⁴⁴ The only clinical trial of gene therapy for RA that involved nonviral gene delivery used the genetic synovectomy approach with DNA encoding the herpes simplex thymidine kinase gene, with one individual being treated.⁴⁶ Two other phase 1 trials in Korea and the United States involved the use of *ex vivo* delivery of TGF- β_1 via retrovirus vectors, and 16 individuals have been enrolled without any adverse events thus far.³⁷

Osteoarthritis

Because IL-1 is also an important mediator of cartilage breakdown in OA, its inhibitors have likewise been considered useful targets for gene

intervention. Several animal studies have confirmed the promise of IL-1ra gene delivery in treating OA.⁴⁷ *Ex vivo* delivery of IL-1ra cDNA via retrovirus vectors and direct delivery of IL-1ra via plasmid DNA to the osteoarthritic knee joints of dogs⁴⁸ and rabbits, respectively, were shown to slow cartilage degeneration. Remarkably, in a similar study in horses in which the effects of adenoviral-mediated gene delivery of IL-1ra for experimental OA were explored, reduced lameness of the horses receiving gene therapy was observed.⁴⁹ Of note, because of the localized pathology in OA, it is better suited for local, intraarticular delivery of gene transfer vectors than RA is, in which a systemic condition is typically present. However, in the late stages of human OA, substantial structural defects have already resulted from long-term cartilage degeneration. It is thus highly unlikely that arresting the progress of the disease with an antiinflammatory and chondroprotective gene such as IL-1ra would be sufficient. Structural repair of the damaged cartilage (e.g., via cell-based tissue-engineering approaches, possibly in combination with gene therapy approaches) will be needed to restore full joint function, as extensively reviewed elsewhere.^{3,5,50}

Osteoimmunology

■ GEORG SCHETT ■ ALINE BOZEC

INTRODUCTION

Two major aspects determine the clinical picture of rheumatic diseases. The first is that inflammation is a central component of many, especially the most severe forms of rheumatic diseases. Some rheumatic diseases, such as rheumatoid arthritis (RA), systemic lupus erythematosus, or Sjögren syndrome, are considered classic systemic autoimmune diseases based on the observation of autoantibody formation and accumulation of cells of the adaptive immune system at sites of inflammation. Chronic immune system activation is regarded as a central triggering factor for inflammatory rheumatic diseases. The second key aspect is that the consequences of the immune disturbances affect musculoskeletal tissue, which is the common target of this disease group. Indeed, musculoskeletal tissue experiences progressive local and systemic damage, which is the basis for functional impairment and a high disease burden. Thus, the combination of chronic immune system activation and musculoskeletal tissue damage is the hallmark of rheumatic diseases. Detailed understanding of the pathophysiologic processes of rheumatic diseases requires comprehension of the mutual interactions between the immune system and musculoskeletal tissue. These interactions are the basis for osteoimmunology.

CURRENT CONCEPTS IN OSTEOIMMUNOLOGY

Osteoimmunology is a field of research that focuses on the crosstalk between the immune and musculoskeletal systems.¹ This field is particularly relevant for understanding rheumatic diseases, which are characterized by profound alterations in bone architecture as a consequence of activation of the immune system. The term *osteoimmunology* was created after landmark observations in the late 1990s demonstrated T lymphocytes triggering bone loss by inducing the differentiation of bone-resorbing cells, termed *osteoclasts*.²⁻⁴ These concepts put two, at first sight fundamentally different, organ systems—the immune system and the skeleton—in a much closer relationship to each other than one would ever expect.

Current concepts of osteoimmunology that are of relevance for rheumatology involve (1) regulation of bone degradation by the immune system, (2) the interaction between inflammation and bone formation, and (3) the role of bone and bone marrow as a niche for immune cells. The first concept, immune-mediated regulation of bone loss, has been studied intensively in recent years and has become a well-developed concept that is instrumental in understanding the different forms of bone loss in the course of rheumatic diseases. In contrast, the second concept, interactions between inflammation and bone formation, is still much less developed but is important for defining the mechanisms of repair of structural damage in the joint and the mechanisms driving general bone loss, as well as for explaining the pathophysiology of bony ankylosis. Similarly, the third concept, the bone marrow niche, is currently being highly investigated and is particularly relevant to understanding the deregulation of immune cell trafficking during inflammatory diseases (i.e., the triggers for recruitment of immune cells from bone marrow into inflammatory sites) and to explaining the formation of a stable microenvironment, which allows longevity and antibody production by long-lived plasma cells.

OSTEOCLASTS AS TRIGGERS OF ARTHRITIC BONE EROSIONS

Erosion of periarticular bone is a central feature of RA and psoriatic arthritis.^{5,6} Bone erosion mirrors the destructive process in joints affected by arthritis because it reflects the damage triggered by chronic inflammation.

Visualization of bone erosions by imaging techniques is important not only for the diagnosis of RA but also for defining the severity of disease and response to antirheumatic therapy.⁷ Osteoclasts are bone-specialized macrophages and are the only cell type capable of removing calcium from bone and, consequently, degrading bone matrix. This bone-resorbing function is an essential component of the bone-remodeling process that allows not only normal bone development and skeletal growth but also bone maintenance and repair throughout life. Osteoclasts are also required for the bone erosions observed in rheumatic joints. Indeed, osteoclasts are part of the inflamed synovial tissue of human RA and psoriatic arthritis, as well as all major experimental models of arthritis. Preliminary evidence for osteoclasts in the synovial tissue of RA patients was gathered in the 1980s before Gravallese and colleagues first described that mature osteoclasts are localized at the site of bone erosions in RA joints by using modern molecular tools for characterization of these cells.^{8,9} Later, the essential function of osteoclasts in triggering inflammatory bone erosions was shown by blocking essential molecules for osteoclastogenesis or by using mice deficient in osteoclasts.^{10,11} In all these models no bone erosions occurred when osteoclasts were either effectively blocked or genetically depleted despite clear synovial inflammation. These findings clearly placed osteoclasts as the effector cells for bone erosions and structural damage downstream from the inflammation in the affected joints.

MOLECULAR AND CELLULAR MECHANISMS OF INFLAMMATORY BONE EROSION

What are the mechanisms leading to osteoclast formation at a site since they are not usually present in the joints? Two key mechanisms are essential to form osteoclasts in joints: (1) accumulation of osteoclast precursor cells in the joint and (2) stimulation of their differentiation into the osteoclast lineage. Osteoclast precursors are mononuclear cells belonging to the monocyte/macrophage lineage.¹² Early monocytic precursor cells have the potential to differentiate into macrophages, dendritic cells, osteoclasts, and other more organ-specific cell lineage types such as Kupffer cells in the liver or microglia in the brain. It is not fully clear whether some monocytes already committed to the osteoclast lineage are entering an inflamed joint or whether monocytes “decide” locally within the inflamed synovium on receiving the appropriate signals to switch to the osteoclast lineage. Nonetheless, experimental evidence supports the observation that the peripheral monocytic pool changes during inflammation. For instance, the fraction of CD11b+ cells that serve as osteoclast precursors increases, thus suggesting that an increased number of cells entering the joint can differentiate into osteoclasts.¹³ Moreover, cytokines such as tumor necrosis factor- α (TNF- α) induce the expression of receptors on the monocyte surface, such as osteoclast-associated receptor (OSCAR), which is important for osteoclast differentiation.¹⁴ However, in actuality much less is known about surface receptors on monocytes that can negatively regulate their differentiation into osteoclasts. In fact, one such molecule is CD80/CD86, which effectively blocks osteoclast formation when bound to CTLA4, a negative regulator of T-cell costimulation by monocytes.^{15,16} This could link regulatory T cells that are highly expressing CTLA4 on their surface to bone homeostasis because these cells can suppress osteoclast formation independently of the receptor activator of nuclear factor κ B (NF- κ B) ligand (RANKL), which is one of the major regulators of osteoclast differentiation.

The second mechanism is that monocytic osteoclast precursors that have already entered the inflamed joints find the ideal environment there to further differentiate into osteoclasts because of the presence of RANKL and monocyte colony-stimulating factor (M-CSF/CSF-1), essential stimulating signals for osteoclastogenesis. Both are also involved in the activation of mature osteoclasts (Fig. 22.1). M-CSF, which binds to CSF-1R encoded by

Fig. 22.1 Monocytic cells in the synovium serve as osteoclast precursors. On exposure to monocyte colony-stimulating factor (M-CSF) and receptor activator of nuclear factor κ B ligand (RANKL) synthesized by T cells and synovial fibroblasts, they fuse to polykaryons, termed *preosteoclasts*, which then undergo further differentiation into mature osteoclasts and acquire specific features such as the ruffled membrane. Inflammatory cytokines such as tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), IL-6, and IL-17 increase the expression of RANKL and thus support osteoclastogenesis in the joint while inhibiting systemic bone formation by the osteoblasts. In contrast, Treg blocks osteoclast formation via CTLA4.

the protooncogene *C-FMS*, promotes both proliferation and survival of osteoclast precursors. RANKL binds a surface receptor on the precursor cells named RANK that induces signaling essential for osteoclast differentiation via NF- κ B and the activator protein 1 (AP-1) transcription factor family.^{2,3} In the joint this process requires intensive crosstalk with other cells, particularly fibroblast-like synoviocytes and activated T cells. Among T cells, both type 1 and type 17 helper subsets are of importance in this process. Indeed, both cell types inducibly express RANKL.^{3,17} This essential osteoclastogenic cytokine is expressed in the synovium of patients with RA, thus suggesting that it actively contributes to formation of osteoclasts in the synovium.^{18,19} A high level of RANKL expression in the synovium is apparently not balanced by the expression of regulatory molecules such as osteoprotegerin (OPG), a decoy receptor of RANKL that blocks osteoclast formation,²⁰ which suggests that this imbalance is of importance in yielding a negative net effect on local bone mass in the case of arthritis. This concept is supported not only by data obtained from animal models of arthritis showing effective protection from structural damage when blocking RANKL with OPG despite clear synovial inflammation but also by a recent clinical study showing that an antibody against RANKL (denosumab) protects against the progression of bony structural damage in patients with RA.²¹

Apart from RANKL, the osteoclastogenic properties of the inflamed synovial membrane are further enhanced by expression of M-CSF, which is essential for osteoclast formation as well.²² Moreover, proinflammatory cytokines such as TNF- α , interleukin-1 (IL-1), IL-6, IL-17, and vascular endothelial growth factor (VEGF) are all potent inducers of RANKL expression and thus enhance osteoclast differentiation as well. Some of these cytokines additionally exert direct effects on osteoclast precursors; in particular, TNF- α engages TNF receptor type I on the surface of osteoclast precursors, which increases their differentiation into osteoclasts.²³ This link between proinflammatory cytokines and osteoclast formation is most likely the explanation why cytokine-targeted therapy, particularly blockade of TNF- α , is highly effective in retarding the structural damage in RA. Indeed, TNF-blocking agents virtually arrest the radiographic damage in RA and are considered excellent agents for achieving structural protection of joints.²⁴⁻²⁹ Furthermore, several studies have shown that anti-citrullinated protein antibodies (ACPAs) are among the strongest predictors of bone-erosive disease in RA, thus linking autoantibody response in RA and the ability of the disease to elicit structural bone damage. Recently, autoantibodies against

citrullinated vimentin have been reported to bind to osteoclasts, induce their differentiation into bone-resorbing cells, and promote bone loss. This effect was based on the inducible release of TNF- α from osteoclast precursors.³⁰

Apart from TNF- α -blocking therapies, one can anticipate a similar effect of the IL-6 antagonist tocilizumab in addition to its well-established anti-inflammatory effect^{31,32} based on the observations that anti-IL-6R antibody therapies reduce VEGF in synovial fibroblast cultures and that IL-6 drives RANKL expression and hence supports osteoclastogenesis.^{33,34}

PERIARTICULAR AND SYSTEMIC BONE LOSS IN RHEUMATIC DISEASE

Periarticular bone loss has been long known as a radiographic sign of RA and has been explained by the paracrine effects of inflammatory tissue on periarticular bone. Still, periarticular bone loss (also termed *periarticular osteoporosis*) has been poorly defined so far. Apparently, periarticular bone loss is based on a substantial decrease in bone trabeculae along the metaphyses of bones close to inflamed joints, thus suggesting that the bone marrow cavity along inflamed joints is also part of the disease process of arthritis. This is supported by data from magnetic resonance imaging (MRI) studies in patients with RA, which have unraveled a high frequency of signal alterations in the juxtaarticular bone marrow in addition to synovitis outside the cortical bone barrier.^{35,36} These lesions are water-rich lesions with a low fat content, which suggests that bone marrow fat is locally replaced by water-rich tissue. Histologic examination of bone marrow lesions has been carried out in joints of patients with advanced-stage RA undergoing joint replacement surgery. They have revealed that the bone marrow lesions visualized on MRI contain (water-rich) vascularized inflammatory infiltrates that replace bone marrow fat and harbor aggregates of B cells and T cells. Importantly, very similar, if not identical MRI changes are found early in the disease process of RA and have shown a link to subsequent bone erosions in the same joints.³⁷ Bone marrow lesions are often linked to cortical penetration of inflammatory tissue either by means of bone erosions or by small cortical bone channels that connect the synovium with the juxtaarticular bone marrow. Moreover, bone marrow lesions are associated with an endosteal bone response since they coincide with the accumulation of osteoblasts and deposition of bone matrix in the endosteum.³⁸ These novel data have enhanced our view of arthritis as a disease that is confined not solely to the synovial membrane but also to bone marrow.

It has long been known that inflammatory diseases, including RA and ankylosing spondylitis (AS), lead to osteoporosis and increased fracture risk. Data obtained in recent years have supported these concepts and have shed more detailed light on osteoporosis and fracture risk in RA patients. Osteopenia and osteoporosis are frequently observed in patients with RA and are even observed in rather high frequency before any disease-modifying antirheumatic drug (DMARD) or glucocorticoid therapy is started. Roughly 25% of patients with RA have osteopenic bone mineral density at the spine or hip before the onset of therapy in early RA, and 10% have osteoporosis, thus suggesting these symptoms to be an intrinsic component of the diseases.³⁹ Consequently, RA patients are at high risk for the development of complications from systemic bone loss because of the increased prevalence of low bone mass at the onset of disease. The reason for this risk appears to be based on the coincidence of standard risk factors for osteoporosis, such as older age and female sex, with the onset of RA. Another explanation is the possibility that low-grade inflammation often long precedes the onset of clinical symptoms of RA. Indeed, even a small elevation in C-reactive protein as a sign of low-grade inflammation in the normal healthy population dramatically increases the risk for fractures, as independent population-based studies have shown.⁴⁰ Fracture risk is in fact higher in RA patients and has been confirmed by a recent meta-analysis of nine prospective population-based cohorts in which it was shown that fracture risk doubles with the diagnosis of RA independent of whether glucocorticoids are used.⁴¹ Similarly, a large case-control study based on the British General Practice Research Database has shown that RA doubles the risk for hip and vertebral fracture, which clearly supports the concept that inflammation is an independent risk factor for osteoporosis.⁴²

OSTEOIMMUNOLOGIC ASPECTS OF BONE FORMATION IN RHEUMATIC DISEASE

To gain a balanced view of the interaction between the immune system and bone it is important to better define how activation of the immune system controls bone formation. Given the observation that inflammatory arthritis induces profound changes in joint architecture—covering the whole

spectrum from an almost purely erosive disease such as RA, to a mixed pattern with erosions and bone formation side by side, to a prominent bone-forming pattern as observed in AS—regulation of bone formation becomes an interesting aspect of rheumatic diseases. In RA, there is little sign of repair of bone erosions, which is astonishing considering that bone formation is usually coupled to bone resorption and that an increased rate of bone resorption should thus increase bone formation. This, however, is by no means the case in RA, which is virtually a purely erosive disease. Recent data suggest that bone formation is actively suppressed by inflammation. Interestingly, TNF- α suppresses bone formation very potently by enhancing the expression of Dickkopf-1 (DKK1), a protein that negatively regulates the wntless/int (Wnt) signal transduction pathway.⁴³ Wnt signals are key triggers for bone formation by enhancing the differentiation of bone-forming cells (i.e., osteoblasts) from their mesenchymal cell precursors. Wnt proteins are also involved in the regulation of osteoclastogenesis because they enhance the expression of OPG, which blocks osteoclast formation.⁴⁴ Thus, influencing the balance of Wnt proteins and their inhibitors is a very potent strategy for disturbing bone homeostasis: a low level of Wnt activity yields low bone formation and high bone resorption, whereas a high level of Wnt activity increases bone formation and simultaneously blocks bone resorption. In RA, the former scenario appears to be relevant because bone resorption is increased and bone formation is decreased. Inhibitors of Wnt, such as DKK1, are expressed in the synovial tissue of RA patients, thus suggesting a suppressive effect on bone formation. This concept is further supported by the paucity of fully differentiated osteoblasts within arthritic bone erosions, which indicates that no major bone formation is indeed occurring in these lesions.

Pure degradation of bone during arthritis is the exception rather than the rule in joint disease. Psoriatic arthritis, AS, and osteoarthritis and metabolic arthropathies such as hemochromatosis arthropathy are partly or even predominantly characterized by bony spurs along joints and intervertebral spaces. These lesions are based on new bone formation. We have recently perceived that osteophyte formation cannot easily be compared with the erosive structural damage observed in RA and that therapies blocking bone erosions such as TNF- α blockade do not influence the formation of osteophytes/syndesmophytes.⁴⁵ Areas prone to osteophyte formation are (1) periarticular sites of the periosteum in the vicinity of the articular cartilage, (2) edges of vertebral bodies, and (3) the insertion sites of tendons. These sites are particularly rich in fibrocartilage, which is considered a tissue from which osteophyte formation emerges given the interplay of certain triggering factors.⁴⁶ Triggers are certainly mechanical factors because osteophytes often emerge at entheses along the insertion sites of the tendons. Usually, osteophytes are based on endochondral ossification, which first leads to differentiation of hypertrophic chondrocytes from mesenchymal cells and abundant deposition of extracellular matrix before rebuilding into bone occurs, a process that requires invasion and resorption of the mineralized cartilage by osteoclasts and then differentiation of osteoblasts that deposit the bone. The molecular signals involved in osteophyte formation have recently been defined: transforming growth factor- β (TGF- β) and bone morphogenetic proteins (BMPs), along with active BMP signaling through SMAD3 proteins, facilitate human osteophyte formation.⁴⁷ Moreover, noggin, an inhibitor of BMPs, effectively blocks osteophyte formation, thus suggesting that this protein family plays a key role in the formation of bony spurs by facilitating osteoblast differentiation.⁴⁷ Another essential protein family involved in osteophyte formation is the Wnt protein family. These proteins bind to surface receptors such as low-density lipoprotein-related protein (LRP) 5/6 and frizzled proteins on the surface of mesenchymal cells, and such binding leads to signaling through β -catenin, which translocates to the nucleus and activates genes involved in bone formation. Nuclear translocation of β -catenin is observed at sites of bony spurs, thus suggesting its activation by Wnt proteins. There appears to be tight crosstalk between Wnt proteins and BMP proteins because these two protein families act synergistically on bone formation. Moreover, crosstalk to the RANKL-OPG system occurs as well because Wnt proteins induce the expression of OPG, which shuts down bone resorption.⁴⁸ It thus appears that the balance between bone-forming factors, such as Wnt and BMP proteins, and bone-resorbing factors, such as RANKL and TNF, is crucial for how a joint remodels during arthritis.

BONE MARROW AS A NICHE FOR B-CELL DIFFERENTIATION AND AUTOANTIBODY FORMATION

Mechanisms that explain the influence of the immune system on bone homeostasis have thus far dominated osteoimmunology research; however,

Fig. 22.2 Bone marrow niche. Maintenance and renewal of hematopoietic stem cells (HSCs) depend on a subset of osteoblasts forming the HSCs' niche, which are defined as spindle-shaped N-cadherin+CD45⁺ osteoblastic (SNO) cells. HSCs are mobilized by the activity of osteoclasts and differentiate. Pre-pro-B cells share a common niche with plasma cells based on the expression of CXCL12 by bone marrow stromal cells, also known as CAR (CXCL12-abundant reticular) cells. On further differentiation into pro-B cells, the cells switch to a different niche that is based on bone marrow stromal cells that express interleukin-7 (IL-7). Further differentiation of B cells into pre-B cells makes them independent of bone marrow niches before leaving the bone marrow to secondary lymphatic organs. Plasma cells reentering the bone marrow share the CXCL12-triggered bone marrow niche with pre-pro-B cells.

bone-immune system interactions also play an important role in other areas. Bone is a hematopoietic organ that provides the microenvironment, also called niches, for the maintenance and mobilization of hematopoietic stem cells (HSCs); it is the site of early B-cell differentiation and homing of the long-lived plasma cells. Despite a high number of studies describing osteoblastic and vascular niches, a novel concept suggests that mesenchymal cells and HSCs form a unique bone marrow niche that is regulated by the local surrounding environment and by long-distance signals such as hormones.⁴⁹ Bone-forming cells, or osteoblasts, have been shown to be required for establishing formation of the HSC niche, and osteoblastic development is regulated by osteoclasts.⁵⁰ These factors appear to be important in early B-cell differentiation, as well as for the survival of long-lived B cells and plasma cells.⁵¹ B cells contribute to RA through antigen presentation and the production of antibodies, autoantibodies, and cytokines. Both the earliest precursors (pre-pro-B cells) and end-stage B cells (plasma cells) require CXC chemokine ligand 12 (CXCL12) to home to bone marrow (Fig. 22.2). CXCL12-abundant reticular (CAR) cells are a small population of bone marrow stromal cells that are the main reason why peripheral HSCs always home to bone marrow. CAR cells are distinct from the mononuclear spindle-shaped N-cadherin+CD45⁺ osteoblastic (SNO) cells that express IL-7 and adjoin more mature pro-B cells.⁵² SNO cells not only allow homing of memory B cells and plasma cells to bone marrow but also provide survival signals that allow longevity of these cells and prevent apoptosis. Thus, long-lived memory B cells and plasma cells are dependent not only on affinity maturation but also on an acquired ability to survive. Successful competition for survival niches therefore appears to be a key factor explaining the longevity of these cells. Plasma cells apparently traffic into these survival niches in bone marrow by CXCL12-induced chemotaxis, where they produce antibodies and persist. If bone marrow homing of plasma cells is disturbed, which is seen in murine lupus models in which plasma cells are unresponsive to CXCL12, a marked accumulation of plasma cells in the spleen is observed.⁵¹ Also, circulating B cells might become only memory B cells if they find appropriate survival conditions outside restimulating secondary lymphoid organs.

CONCLUSION

Osteoimmunology has considerably refined our insights into the pathogenesis of rheumatic diseases, particularly arthritis. It appears that one of the

reasons for the preferential targeting of bone by inflammatory arthritis is a disturbance in the natural interaction of the bone and immune systems. This idea gives credence to the old concept of bone remodeling as a controlled inflammatory response despite clear synovial inflammation.⁵³ With the help of osteoimmunology, we are now starting to understand the molecular interactions between immune activation and the skeletal system, which

links inflammatory diseases with bone loss. Knowledge of these pathways will allow tailoring of drug therapies to target skeletal damage more specifically and thus more effectively. In addition, further insight in the role that bone and bone marrow play in shaping the immune responses, particularly in maintaining plasma cells in the bone marrow niche, will open a new perspective in autoimmune diseases.

Inflammation and its mediators

■ ARYEH M. ABELES ■ MICHAEL H. PILLINGER ■ STEVEN B. ABRAMSON

- Inflammation is the primary process by which the body attacks and destroys microbial invaders, heals wounds, and damages its own tissues.
- The acute, or early, phase of inflammation is characterized by microvascular changes and activation of granulocytic cells (neutrophils, mast cells, eosinophils). Cells from the monocytic lineage predominate in the mature or chronic inflammatory response.
- Activation of platelets and endothelial cells is an essential element of the inflammatory response in tissues.
- Among the most important plasma-derived mediators of inflammation are complement components that provoke vasodilation, granulocyte chemotaxis, and the secretion of inflammatory cell mediators.
- Soluble mediators released from activated cells promote inflammation and provoke tissue injury. Such mediators include histamine and serotonin, prostaglandins and leukotrienes, superoxide anion, and nitric oxide.
- The inflammatory response involves a complex interaction between the nervous system and inflammatory cells.

INTRODUCTION

Inflammatory processes are necessary for survival and regulate both homeostasis of the organism and defense against pathogens. Best recognized as a localized response to injury (e.g., from microbial pathogens, trauma, neoplasia, toxins), inflammation is also important in tissue remodeling during development and in clearance of cellular debris during tissue turnover.

For two millennia, inflammation has been clinically recognized by the four cardinal signs of Celsus: calor (heat), rubor (redness), dolor (pain), and tumor (swelling). A fifth sign, *functio laesa* (loss of function), was proposed by the 19th century pathologist Virchow to underscore inflammation's potential to cause damage. At the cellular level, inflammation begins with vasodilation and increased microcirculation, which leads to transmigration of leukocytes into the injured tissue.¹ Inflammation involves interplay of the innate and adaptive immune responses, the immunologic and nervous systems, and the coagulation and fibrinolytic cascades. Inflammatory responses are regulated, in a complex and integrated manner, by the effects of a wide range of molecular mediators. These inflammatory mediators are highly diverse but can be grouped loosely as (1) growth factors and cytokines, (2) arachidonic acid (AA) derivatives and lipid mediators, (3) the complement system, (4) proteases, (5) neuropeptides, and (6) free radicals and reactive oxygen species (ROS).

In health, inflammation is a self-limited response to a specific injury; once the injury is repaired, the inflammatory focus clears and homeostasis is restored. On occasion, however, the inflammatory response is triggered inappropriately or excessively or it fails to resolve after the trigger is removed. Excessive inflammation may result, for example, in response to a persistent host antigen being misinterpreted as foreign (e.g., in rheumatic fever or poststreptococcal glomerulonephritis) or from a decreased ability to clear immune system stimulants such as apoptotic cells or immune complexes (as in systemic lupus erythematosus [SLE]); in these cases, autoimmune responses drive undesirable and frequently destructive inflammation. In other, so-called autoinflammatory syndromes (e.g., familial Mediterranean fever), inflammatory cells themselves may have defects that lead to persistent or recurrent undesirable inflammation. In many cases we do not fully understand what causes pure inflammatory diseases. Nonetheless, our understanding of inflammatory processes has increased remarkably, which

has led to targeted therapies for inflammatory diseases, including agents that block the proinflammatory cytokines tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and IL-6, as well as agents targeted to other inflammatory mediators. The more that we learn about the processes of inflammation, the more likely that effective therapies will be developed for rheumatic and other inflammatory diseases.

Here we summarize the major cellular participants in inflammation and provide an overview of the mediators that drive inflammatory responses.

THE CELLS OF INFLAMMATION

Acute versus chronic inflammation

Inflammation can be either acute or chronic. The acute, or early, phase of inflammation is characterized by microvascular changes and neutrophilic infiltration, whereas monocytic cells predominate in the chronic inflammatory response. These distinctions are somewhat arbitrary, however, with many exceptions. For example, cells of the monocytic lineage may dominate from the beginning of an inflammatory response (as in tuberculosis), and neutrophils persist in some forms of chronic inflammation (as in polyarteritis nodosa). Resident tissue macrophages from the monocytic line may also provide the early sentinel signals that initiate acute inflammation, as is the case with gout and pseudogout.²

Endothelial cell activation

Many of the leukocytes that participate in inflammation circulate in the bloodstream. To localize to extravascular tissue, they must exit the vasculature (diapedesis) and migrate to the extravascular space (chemotaxis). These processes require a complex sequence of events, beginning with the (micro)vascular response. Arterioles vasodilate and endothelial cells contract, thereby exposing the basement membrane; blood flow slows and plasma extravasates. In turn, leukocytes concentrate and increase their contact with the endothelium.³

In response to bacteria or other affront, resident tissue immune cells (macrophages, dendritic cells, and fibroblasts) generate mediators such as IL-1 β and TNF- α . These cytokines (Greek for "cell movers") induce local vascular endothelial cells to express surface molecules that contact and bind leukocytes, which permits their egress from the vasculature.⁴ Diverse pairs of adhesion molecules sequentially mediate leukocyte rolling, tight adhesion, and diapedesis (Fig. 23.1). The first step, leukocyte rolling, occurs mainly via interactions of the adhesion molecules E-selectin on endothelial cells and L-selectin on leukocytes with mucin-like sialylated glycoproteins on leukocytes and endothelial cells, respectively.⁴ Selectins are expressed constitutively on both leukocytes and endothelium, and their interactions are strong but short-lived, with the result that a percentage of leukocytes are always transiently adherent, or marginated, to the endothelium and roll along with a tumbleweed-like progression. At sites of inflammation, after exposure to stimuli such as IL-1 β and TNF- α , expression of E-selectin on endothelial cells increases markedly, which leads to an increase in the percentage of leukocytes that marginate and roll. The next step, leukocyte tight adhesion, results from the interaction of leukocyte adhesion molecules known as integrins (e.g., CD11a/CD18 or LFA-1, CD11b/CD18 or CR3, $\alpha_5\beta_1$, or VLA-4) with endothelial cell counterligands (e.g., intercellular adhesion molecule-1 [ICAM-1] and vascular cell adhesion molecule-1 [VCAM-1]). Tight adhesion requires the *de novo* expression of adhesion molecules on endothelium and activation of preexisting integrins on leukocytes, both in response to inflammatory mediators. Specific integrin-ligand pairing, in turn, establishes specific cell-cell adhesion events that contribute

Fig. 23.1 Leukocytes exit the vasculature through a sequence of interactions with the vascular endothelium. The first step, rolling, guarantees leukocyte-endothelial contact through transient interactions between selectins and sialylated glycoproteins (sialyl-Lewis^x) on cognate cells. Leukocyte tight adhesion results from the interaction of leukocyte adhesion molecules known as integrins with counterligands on endothelial cells, such as intercellular adhesion molecule 1 (ICAM-1). In contrast to selectin/glycoprotein interactions, integrin/ICAM interactions are dependent on activation and expression. Once tightly adherent to the endothelium, leukocytes transmigrate through the vasculature and into tissues. Activation of leukocytes, as well as their transmigration through the endothelium and basement membrane, is mediated by chemoattractants such as monocyte chemoattractant protein 1 (MCP-1), C5a, *N*-formyl-methionyl-leucyl-phenylalanine (fMLP), leukotriene B₄ (LTB₄), and interleukin-8 (IL-8). TNF- α , tumor necrosis factor- α .

to the distribution and homing of leukocytes; common integrin-ligand pairs include CD11a/CD18 with ICAM-1 (lymphocytes-endothelium), CD11b/CD18 with ICAM-1 (neutrophils-endothelium), and VLA-4 with VCAM-1 (monocytes-endothelium). Importantly, many of these adhesion molecules are not inert binders of their cognate ligands; for example, CD11b/CD18 (also known as macrophage 1 antigen and complement receptor 3) is not only an adhesion molecule but also a receptor for the “inactive” form of the C3b complement component (C3bi), as well as a transmembrane signaling receptor in its own right. Finally, transmigration of leukocytes through the endothelium and basement membrane is driven by chemokines such as monocyte chemoattractant protein-1 (MCP-1), C5a, and IL-8.¹

Granulocytes

Neutrophils, eosinophils, and basophils constitute a group of leukocytes known as granulocytes, so named for the presence of highly visible granules—actually highly developed vacuolar structures—in their cytoplasm (Fig. 23.2). Mast cells are similarly equipped with specialized granules but are classified separately. The contents of the granules vary with cell type and can be distinguished under routine staining (hematoxylin-eosin) with light microscopy. Granulocytes, also called polymorphonuclear leukocytes because of their multilobed nuclei, form a part of the innate immune system and are crucial to the acute inflammatory response.

Neutrophils

Polymorphonuclear neutrophils are the body's first-line defense against most foreign invaders and are the major cell type in most acute and some chronic inflammatory diseases. The importance of neutrophils in bacterial defense is demonstrated by patients with hereditary defects in neutrophil

function, who are prone to repeated and often life-threatening infections. Neutrophils are the most prevalent leukocyte in the bloodstream and account for more than 50% of all circulating white blood cells; in acute inflammatory conditions (e.g., bacterial infection), the percentage of neutrophils in the bloodstream increases to 80% or greater. Unlike most other leukocytes, however, neutrophils are not normally present in significant numbers in the extravascular spaces. Neutrophils are also remarkable for their short half-life, approximately 7 hours inside the bloodstream and slightly longer in extravascular spaces.

Neutrophil granules contain an impressive arsenal of microbicidal weaponry that is unleashed on cell activation (Figs. 23.3 and 23.4). As identified by routine staining, neutrophil granules consist of two classes: primary (or azurophilic) granules develop first, followed by secondary (or specific) granules. *Azurophilic granules* are functionally similar to the lysosomes of other cells. Like other lysosomes, azurophilic granules contain a variety of proteases, in this case including elastase, matrix metalloproteinase-3 (MMP-3), MMP-8, MMP-9, cathepsins, and lysozyme (Table 23.1). In addition, azurophilic granules contain myeloperoxidase (MPO), a key enzyme for both microbicidal activity and mediation of tissue injury in inflammatory disease. In response to phagocytosis of a bacterium or other foreign body, azurophilic granules fuse with the phagosome to direct their contents at the ingested target. In addition, a membrane-bound reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is assembled and activated, which results in rapid oxygen consumption (the “respiratory burst”) and the generation of potent ROSs within the phagolysosome. Coordinated discharge of MPO from the azurophilic granule into the phagolysosome catalyzes the reaction of ROSs and chloride to form hypochlorous acid (HOCl, or chlorine bleach). HOCl and its derivatives are powerful oxidizing agents that can, among other things, disrupt bacterial electron transport

Fig. 23.2 Leukocyte micrographs (light microscopy, hematoxylin-eosin). (a) A neutrophil, or polymorphonuclear leukocyte. Note that the cytoplasm stains bluish and appears granular secondary to the staining properties of the azurophilic granules. Neutrophils typically have nuclei with three to five lobes; four lobes are seen here. (b) An immature neutrophil, known as a band cell because of the distinctive nuclear shape. Such cells are frequently released prematurely from bone marrow during acute inflammatory events. (c) An eosinophil, with pink (eosinophilic) granules and a nucleus with two lobes. Eosinophils have multiple lobes but typically fewer than seen in neutrophils. (d) A monocyte. Note the lack of obvious cytoplasmic granules, the unilobular nucleus, and the monomorphic nucleus and irregular shape. (Figure produced with permission of Harold Ballard, MD.)

Fig. 23.3 Electron micrographs of neutrophils at rest and after stimulation with *N*-formyl-methionyl-leucyl-phenylalanine (fMLP). These electron micrographs highlight the active process of neutrophil disorgement. When activated, the cell surface of the neutrophil ruffles as granules and lysosomes merge with the cell surface to release their contents into the extracellular environment. (a and b) Scanning electron micrographs of a resting neutrophil and activated neutrophil, respectively. (c and d) Transmission electron micrographs of the same. Note the numerous empty spaces within the cytoplasm of the activated neutrophil; these are indicative of emptied-out granules and the resultant expanded surface membrane. (Figures produced with permission of Gerald Weissmann, MD.)

chains and disturb DNA synthesis. Azurophilic granules thus provide potent mechanisms through which microorganisms are destroyed; when released inappropriately into the extracellular environment, however, the contents of these granules can cause significant tissue damage.

Specific granules also contain lysozyme, but their contents generally differ greatly from those of azurophilic granules. Specific granule proteases include collagenase (MMP-1) and plasminogen activator; they also contain proteins with poorly defined function, such as lactoferrin and β_2 -microglobulin. In contrast to azurophilic granules, specific granules possess an extensive array of membrane-associated proteins, including cytochromes, signaling

molecules, and receptors; thus, specific granules constitute a reservoir of proteins destined for the topologically external surfaces of both phagocytic vacuoles and the plasma membrane.³

In addition to primary and secondary granules, studies have identified two other types of neutrophil granules. *Gelatinase granules*, similar to specific granules in size, are notable for their high concentrations of gelatinase, a latent enzyme with the capacity for tissue destruction. *Secretory vesicles* are smaller than the other granules and do not appear to contain proteolytic enzymes. In contrast to the other granules, which typically fuse with phagolysosomes, secretory granules fuse with the cell membrane and appear to serve as a reservoir for surface membrane lipids and surface membrane-associated proteins.

Because neutrophils have such destructive capacity, localization and activation of them must be carefully regulated. Chemoattractants for neutrophils include leukotriene B₄ (LTB₄), platelet-activating factor (PAF), IL-8, and the complement split product C5a. At low concentrations and when distributed in a gradient, these molecules lead neutrophils to migrate toward regions of higher concentration. At high concentrations, however (i.e., at the bacterial source of the gradient), these same molecules cause neutrophils to cease migration and become activated. Receptors for soluble ligands other than chemoattractants have also been identified on neutrophils, including receptors for growth factors, colony-stimulating factors, and cytokines (see Fig. 23.4); these ligands may modulate neutrophil function. For example, pretreatment of neutrophils with either insulin or granulocyte-macrophage colony-stimulating factor results in the amplification of subsequent neutrophil responses to chemoattractants.³

Once localized to their target tissue and activated, neutrophils are intrinsically inefficient at phagocytosing unmodified targets. Optimal neutrophil phagocytosis depends on opsonization (from the Latin “to prepare for eating”) and modification of a target via adornment of it with immunoglobulin, complement components, or both. Neutrophils express the complement receptors CR1 and CR3, which promote phagocytosis by binding the target-adherent complement components C3b and C3bi, respectively. In addition, neutrophils express two families of receptors for the Fc portion of bound or aggregated IgG: low-affinity Fc γ RIIa and high-affinity Fc γ RIIIb. During some infections or after *in vitro* stimulation with interferon or granulocyte colony-stimulating factor, neutrophils also express the high-affinity receptor Fc γ RI, which binds monomeric IgG (for an overview of leukocyte receptors see Table 23.2).

Recently, a completely novel neutrophil function has been identified. In some instances, neutrophils confronted with bacterial invasion may choose to die and in so doing release neutrophil extracellular nets (NETs), which are composed of decondensed chromatin associated with antimicrobial proteins. NETs have the capacity to trap and kill bacteria and serve both as a physical containment structure to prevent bacterial spread and as an antibacterial delivery system. NETs may also serve as a “catalytic” surface on

Fig. 23.4 Various signals stimulate neutrophil activation via ligation of cell-surface receptors. On activation, neutrophils both degranulate and produce a number of inflammatory mediators. See text for details. BLT, leukotriene B₄ receptor; BPI, bactericidal/permeability-increasing protein; fMLP, *N*-formyl-methionyl-leucyl-phenylalanine; FPR, formyl peptide receptor; ICAM-1, intercellular adhesion molecule 1; IL-8, interleukin-8; LPS, lipopolysaccharide; LTB₄, leukotriene B₄; TLR4, Toll-like receptor 4.

TABLE 23.1

Products of neutrophils, macrophages, and eosinophils

Cell	Granule contents	Cytokines produced	Other inflammatory mediators
Neutrophil	<i>Primary (azurophilic) granules:</i> Elastase, MMP-3, MMP-8, MMP-9, cathepsins, defensins, bactericidal/permeability-increasing protein, proteinase 3, lysozyme, myeloperoxidase <i>Secondary (specific) granules:</i> Collagenase, plasminogen activator, lysozyme, lactoferrin, β_2-microglobulin <i>Gelatinase granules:</i> Gelatinase	IL-1, L-6, IL-8, TNF- α , GM-CSF	ROS, PAF, PGE ₂ , LTB ₄
Macrophage	Lysozyme (aside from many others mentioned in text)	IL-1 β , TNF- α , IL-6, IL-8, IL-12, MCP-1, MCP-2, RANTES, PDGF, TGF- β , IFN- γ	Complement components, ROS, iNOS, PGE ₂ , TxA ₂ , PGI ₂ , LTB ₄ , LTC ₄ , PAF, MMP-1, tissue factor, plasmin inhibitor
Eosinophil	<i>Specific granules:</i> Charcot-Leyden crystal protein, major basic protein, eosinophil peroxidase, eosinophil cationic protein, eosinophil-derived neurotoxin, secretory PLA₂ <i>Small granules:</i> Arylsulfatase B	IL-4, IL-5, IL-8, IL-10, IL-12, GM-CSF, TNF- α , TGF- β , LTB ₄ , LTC ₄ , PAF, PGE ₂ , ROS, collagenase, PDGF, VEGF, MCP-1	

GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon- γ ; IL-1, interleukin-1; iNOS, inducible nitric oxide synthase; LTB₄, leukotriene B₄; MCP-1, monocyte chemoattractant protein-1; MMP-3, matrix metalloproteinase-3; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PGE₂, prostaglandin E₂; RANTES, regulated on activation, T cell expressed and excreted; ROS, reactive oxygen species; TNF- α , tumor necrosis factor- α ; TXA₂, thromboxane A₂; VEGF, vascular endothelial growth factor.

TABLE 23.2
Leukocyte receptors, ligands, and their functions

Receptor type	Examples	Examples of ligands	Functions
FcγR	FcγRI, FcγRIIa, FcγRIIIb	Immunoglobulins	Recognize and bind Fc portions of immunoglobulins
Toll-like receptors	TLR1 to TLR11	Pathogen-associated molecular patterns (PAMPs; e.g., LPS)	Recognize pathogens and activate immune responses
Formyl peptide receptors	Formyl peptide receptor 1	Bacterial <i>N</i> -formyl-methionyl peptides	Mediate chemotaxis and activation of neutrophils and monocyte-macrophages
Scavenger receptors	Scavenger receptor A	Numerous targets on bacteria, apoptotic cell structures	Stimulate phagocytosis of bacteria and apoptotic cells, adhesion
Mannose receptor	Mannose receptor C type 1	Mannose (on pathogens)	Mediates endocytosis of glycoproteins by phagocytes
Complement receptors	CR1, CR2, CR3, CR4 C5aR	Complement components C5a	Aid in opsonization and phagocytosis Activates inflammatory cells
Integrins	Mac-1 (CD11b/CD18) LFA-1 (CD11a/CD18)	ICAM-1	Bind to cell adhesion molecules and extracellular matrix, which results in strong adhesion
Chemokine receptors (CR, CCR, CXCR, CXXCR classes)	CCR: CCR1 CCR3, CCR5 CXCR: CXCR1, CXCR2	CC: MCP-1, RANTES, MIP-1α CXC: IL-8	Recognize chemoattractants, mobilize and activate leukocytes

ICAM-1, intercellular adhesion molecule-1; LFA-1, lymphocyte function–associated antigen-1; LPS, lipopolysaccharide; MCP-1, monocyte chemoattractant protein-1; MIP-1α, macrophage inflammatory protein-1α; TLR1, Toll-like receptor 1.

which neutrophil elastase can inactivate tissue factor pathway inhibitor, which promotes clotting and possibly contributes to the role of neutrophils in acute coronary syndromes. How neutrophils “decide” whether to use their more classic defense systems or to die and produce NETs remains an area of intense study.⁵

Eosinophils, basophils, and mast cells

Other granulocytes important in inflammatory responses include eosinophils and basophils. Like neutrophils, these cells also contain a variety of lipid and peptide mediators (see Table 23.1). In contrast to neutrophils, however, these cells are less common in the bloodstream but are found in greater numbers in extravascular tissue. Eosinophils typically do not phagocytose their targets but are thought to discharge their contents after adhering to larger surfaces. Eosinophils are considered to be important in combating parasitic infection and are also involved in the inflammatory response generated by allergic or immediate hypersensitivity reactions; the latter role is shared by mast cells and basophils. Abnormal eosinophil activity has been implicated in several inflammatory diseases, including asthma, eosinophilic pneumonia, Churg-Strauss vasculitis, and idiopathic hypereosinophilic syndrome. Basophils also play a role in allergic reactions.

Mast cells are most commonly localized to perivascular locations within tissues. Their granular contents are similar to those of basophils, and like basophils, mast cells may play a role in allergic reactions. Recent data from animal models suggest that mast cells may also be important in the pathogenesis of rheumatoid arthritis (RA).

Macrophages

Macrophages play multiple roles in inflammation and immunity by serving both as antigen-presenting cells (APCs) that drive adaptive immune responses and as primary inflammatory cells in chronic diseases such as atherosclerosis and RA. Tissue macrophages are derived from circulating monocytes but differentiate and become activated on entering peripheral tissues. Although the process of monocyte adhesion to and diapedesis through blood vessels is similar in many respects to that of neutrophils, monocytes respond to a different set of chemotactic factors, including the chemokines RANTES, MCP-1, macrophage inflammatory protein-1α (MIP-1α), and MIP-1β and the growth factors transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) (see Table 23.1).⁶ Once in tissues, macrophages can live for up to several months.

As actors in the innate immune system, macrophages are stimulated to phagocytose nonencapsulated bacteria via recognition of evolutionarily conserved motifs on bacterial surfaces. To do so, macrophages express surface receptors for pathogen-associated molecular patterns, including Toll-like receptors, formyl peptide receptors, and scavenger receptors, many of which are also found on neutrophils (Table 23.2).⁷ After phagocytosis, macrophages destroy microbes through mechanisms similar to those used by neutrophils: lysosomal enzymes, reactive oxygen and nitrogen intermediates, toxic radicals, and chloramines. As with neutrophils, macrophage phagocytosis and killing of pathogens are greatly enhanced by opsonization

of the pathogens. Macrophages have surface receptors for multiple opsonins, including the mannose receptor (which directly recognizes glycoproteins on microbial surfaces), CR1, CR3, CR4, FcγRI, FcγRII, and FcγRIII (see Table 23.2).^{8,9} Although the function of the majority of macrophage products is primarily to augment inflammation and repel external threats, macrophages, like neutrophils, have the capacity to damage host tissue via release of their digestive and degradative contents.

Macrophages differ from neutrophils in their capacity to serve as “professional” APCs. After phagocytosis, APCs degrade foreign antigens in protease-containing endosomes; vesicles containing major histocompatibility complex (MHC) class II molecules then fuse with the endosomes, which allows membrane-bound MHC class II complexes to become loaded with antigenic peptide fragments. The MHC class II/peptide complexes are then delivered to the cell surface, where they present antigen to T cells to stimulate the highly specific responses of adaptive immunity. In this and other examples, the past decade of research has underlined the direct connection between inflammation and innate immunity and their influence on adaptive immune processes.

One of the earliest steps in most inflammatory responses is activation of resident tissue macrophages, whose subsequent production of cytokines alters vasomotor tone and endothelial adhesiveness (as described earlier). Through ligation of various surface receptors, macrophages may be activated by interferon-γ (IFN-γ), complement components, immune complexes, lipopolysaccharide (LPS), and cytokines such as IL-1β, TNF-α, and IL-6.⁷ Once activated, macrophages secrete a dazzling variety of proinflammatory products (see Table 23.1), including proteases (e.g., lysozyme, elastase, and collagenase), inflammatory cytokines (IL-1β, TNF-α, IL-6, IL-12, and others), chemokines (IL-8, MCP-1, MCP-2, RANTES, and others), and several complement cascade proteins (C1, C2, C3, and C4).⁶ Indeed, a vigorous acute-phase response driven by cytokine production and characterized by high serum levels of acute-phase reactants is typical of diseases with extensive macrophage involvement. Activated macrophages also produce multiple eicosanoids (e.g., prostaglandin E₂ [PGE₂], thromboxane A₂ (TXA₂), prostacyclin [PGI₂], LTB₄) that can contribute to the propagation of inflammation. In addition, activated macrophages produce procoagulant factors such as tissue factor and plasmin inhibitor, thereby linking the inflammatory and clotting responses. Indeed, local intravascular coagulation in response to infection is thought to play a role in limiting the spread of infection; when unchecked, coagulation in the presence of inflammation leads to disseminated intravascular coagulation, a potentially life-threatening condition.

Lymphocytes

For a discussion of lymphocytes, please refer to Chapter 15.

Platelets

Platelets are small, anucleated circulating cellular fragments that function to maintain hemostasis. In response to vascular injury, platelets adhere to

the subendothelial matrix of the vascular wall, become activated, and rapidly induce platelet aggregation and thrombus formation. The almost explosive nature of thrombotic events is largely due to platelet degranulation, wherein platelets disgorge preformed factors from α -granules and dense granules into the surrounding microvasculature. In addition to procoagulant factors such as von Willebrand factor, fibrinogen, and factor V, platelet granules also contain inflammatory mediators, including chemokines (e.g., RANTES, MCP-3, MIP-1 α , and platelet factor 4), growth factors (e.g., PDGF and TGF- β), histamine, and serotonin.¹⁰ Further underscoring the link between inflammation and coagulation, platelets are themselves activated on exposure to inflammatory mediators.

Activated platelets not only release preformed inflammatory mediators but also participate in inflammatory processes via plasma membrane activity. Signaling molecules upregulated on activated platelets include P-selectin, which adheres to and activates neutrophils, and CD40L, which induces inflammatory responses in many cell lines, including the endothelium.¹¹ On activation, platelets also rapidly produce eicosanoids, such as TXA₂ from membrane-derived AA, and other lipid membrane-derived inflammatory products, such as PAF. As discussed below, platelets may also participate in some antiinflammatory activities.

Other links between coagulation and inflammation

Inflammation promotes coagulation through additional means. Tissue factor, which stimulates thrombin formation, is produced by macrophages in inflammatory conditions such as sepsis and atherosclerosis.¹² Systemic inflammation also inhibits the function of the natural anticoagulant pathways of antithrombin and protein C. Additionally, systemic inflammation inhibits fibrinolysis via generation of plasminogen activator inhibitor type I (PAI-I). Inhibition of fibrinolysis is permissive for microvascular thrombosis; PAI-I inhibition prevents both endotoxin-induced microthrombosis and experimental coronary thrombosis. Conversely, studies by Salmon and Girardi have implicated complement activation (see later) as a key player in the evolution of antiphospholipid syndrome.¹³ In short, inflammation and coagulation are intimately related processes, and the role of coagulation needs to be considered when treating systemic inflammatory illnesses.

INFLAMMATORY MEDIATORS

A myriad of soluble mediators coordinate the inflammatory process. These mediators are derived from a number of sources, including the inflammatory cells described earlier, plasma proteins, and resident tissue cells such as nerves and endothelium. Some of the more important molecular components are described here.

The complement cascade

Complement was discovered by Bordet in 1899 and described as a heat-labile component of fresh plasma that “complemented” the ability of antibodies to lyse red blood cells and bacteria. More than 30 serum proteins and cell-surface receptors are now collectively recognized as the complement system. A primary function of complement is to coat and opsonize cell membranes and soluble antigens for recognition and digestion by phagocytic cells. Other components generated during complement activation independently generate an inflammatory response. These so-called anaphylatoxins (C3a, C5a) rapidly induce vasodilation, leukocyte activation, and chemotaxis. A third function of the system is to directly lyse unencapsulated, gram-negative bacteria.

Three distinct complement cascades—the classical, alternative, and mannose-binding lectin pathways—differ in their mechanisms of target recognition and initial activation but converge at the C5 convertase (Fig. 23.5). Many complement plasma proteins are zymogens (proteases that become active after proteolytic cleavage) and generally circulate in a dormant state. Once active, many complement components participate in cleavage or activation of subsequent components. Thus, each successive enzymatic step results in rapid and dramatic amplification. In response to this potential for explosive activation, complement regulatory molecules exist to dampen the cascades. Given the importance of complement activation to rheumatic disease, a more detailed understanding of the three complement cascades is important for both researchers and practicing rheumatologists.

Classical pathway

Although it was the first of the three complement pathways to be discovered, the classical pathway was the last to evolve and largely depends on a preceding humoral immune response for its activity. Activation of the classical

pathway occurs when the C1q component of the multimeric complement 1 complex (C1) binds to the Fc tails of multiple IgG or IgM antibodies complexed to antigen. When at least two of the six C1q globular heads have bound, the remaining components of the complex (two molecules each of C1r and C1s) undergo a conformational change that unleashes the autocatalytic enzyme activity in C1r. Active C1r cleaves C1s to its active form. C1s in turn cleaves soluble C4 and then C2 to C4a and C4b and C2a and C2b, respectively.¹⁴ (By convention, cleaved components are designated with the letter “a” for the smaller, soluble fragment and “b” for the bigger, enzymatically active fragment. Complement molecules in the classical pathway are numbered in the order in which they were discovered, which in almost all cases corresponds to their place in the complement sequence. Unfortunately for students, C4 acts before C2 but was discovered after C3.) C4b and C2b combine to form C4b2b (the C3 convertase of the classical pathway), which cleaves C3 to C3a and C3b. C3b combines with C4b2b to form C4b2b3b (C5 convertase), which in turn cleaves C5 to C5b and C5a. Subsequent assembly of the C5b, C6, C7, C8, C9 membrane attack complex (MAC) can form a pore in the cell membrane of some pathogens and most host cells and lead to their death. C3 performs double duty: although some portion of C3b joins with C4b2b to form the C5 convertase, the majority of C3b (as C3b or C3bi) serves as an opsonin; minutes after activation of the complement cascade, millions of C3b molecules are covalently attached to a single bacterium’s surface to facilitate its phagocytosis by macrophages and neutrophils.

Mannose-binding lectin pathway

The mannose-binding lectin (MBL) pathway evolved before the classical pathway and appears to have given rise to the latter. In contrast to the classical pathway, the MBL pathway does not require immunoglobulin but is activated by contact with bacterial surface mannose residues. Because these residues are inaccessible on vertebrate cells, the MBL pathway distinguishes “self” from “other” on the basis of a generic pattern rather than a specific antigen. When a C1q-like component of the MBL complex engages mannose on a pathogen, it activates the mannose-associated serine proteases MASP-1 and MASP-2 (analogous to C1r and C1s); thereafter, the MBL complex functions identical to activated C1: it cleaves C4 and C2 to form the classical C3 convertase.¹⁵

Alternative pathway

The alternative pathway is unique in that its activation is not initiated by binding; instead, the alternative pathway is always undergoing activation via the spontaneous hydrolysis of C3 in plasma. C3(H₂O) binds the alternative pathway component factor B, which is then converted by the associated factor D into Ba and Bb. The C3(H₂O)-Bb complex that results is an alternative C3 convertase and converts fluid-phase C3 into C3a and C3b, the latter of which is quickly inactivated by hydrolysis unless it is deposited on a cell surface. Once covalently bound to a cell surface (or indeed, any surface), however, C3b binds factor B; cleavage of factor B by factor D then results in formation of the membrane-associated C3bBb convertase, which is functionally equivalent to the classical C3 convertase (C4b2b).¹⁶ Because this primitive pathway fails to distinguish self from other, its specificity resides not in any intrinsic property of foreign particles but in the ability of host cells (but not bacteria) to defend themselves against indiscriminate complement activation (see the later section on complement regulation).

C3a and C5a anaphylatoxins

Release of the soluble fragments C3a and C5a, known as anaphylatoxins, accelerates the inflammatory response in multiple ways: anaphylatoxins engage mast cell and basophil receptors, which triggers the release of vasoactive mediators such as histamine and the cysteinyl leukotrienes LTC₄ and LTD₄. C5a and C3a also induce vasodilation and capillary permeability, upregulate adhesion molecule expression on leukocytes and endothelium, and cause smooth muscle contraction. C5a is a powerful chemoattractant and activator of neutrophils and can stimulate both neutrophil degranulation and the respiratory burst.

Complement regulation

When C3bBb binds to host cells, the host complement regulatory proteins CR1 and decay-accelerating factor (DAF) rapidly bind C3b and displace Bb. CR1 and DAF, in combination with the membrane cofactor of proteolysis, also catalyze the cleavage of C3b by plasma protease factor I to produce inactive C3b. In contrast to host cells, bacterial surfaces lack these regulatory proteins and instead permit binding of properdin, which stabilizes rather than degrades the alternative C3 convertase. Thus, bacteria are vulnerable to attack by the alternative pathway by virtue of their inability to defend themselves against complement deposition.

Fig. 23.5 Three distinct complement cascades—the classical, alternative, and lectin pathways—differ in their mechanisms of target recognition and initial activation but converge at the C3 convertase. Activation of the classical pathway occurs when the C1q component of C1 (which consists of C1q, two molecules of C1r, and two molecules of C1s) binds to multiple Fc portions of IgG or IgM antibodies complexed to antigen. Binding of C1q activates C1r, which in turn cleaves C1s to its active form. C1s then cleaves soluble C4 and C2 to C4a and C4b and C2a and C2b, respectively. C4b and C2b combine to form C4b2b (the C3 convertase of the classical pathway), which cleaves C3 to C3a and C3b. C3b combines with C4b2b to form C4b2b3b (C5 convertase), which then cleaves C5 to C5b and C5a. Subsequent assembly of the C5b, C6, C7, C8, C9 membrane attack complex occurs. The mannose-binding lectin pathway is a primitive version of the classical cascade. When the mannose-binding lectin (MBL) component of the MBL complex (analogous in form and function to the C1 complex) binds mannose on a pathogen, it activates the mannose-associated serine proteases MASP-1 and MASP-2 (akin to C1r and C1s); thereafter, the MBL complex functions as activated C1 does by cleaving C4 and C2 to form C3 convertase. The alternative pathway is initiated by the spontaneous hydrolysis of fluid-phase C3. C3 (H₂O) binds the alternative pathway component factor B, which is then converted by the associated factor D into Ba and Bb. The C3(H₂O)-Bb complex that results is an alternate C3 convertase and converts fluid-phase C3 into C3a and C3b, the latter of which is quickly inactivated by hydrolysis unless it is deposited onto a cell surface. If bound to a cell surface, however, C3b can bind factor B; factor D then cleaves factor B, thereby resulting in formation of the C3 convertase C3bBb, which is equivalent to the C3 convertase (C4b2b) of the classical and lectin pathways. (Adapted from Walport MJ. *Advances in immunology: complement (first of two parts)*. *N Engl J Med* 2001;344:1058–61.)

TABLE 23.3
Complement regulatory proteins

Protein	Complement regulatory function	Comments
C1 inhibitor (C1 INH)*	Membrane-bound serine protease inhibitor that inactivates the C1 complex by binding to C1r and C1s	Deficiency associated with hereditary and acquired angioedema, systemic lupus erythematosus
C4-binding protein (C4BP)	Plasma protein that displaces C2b and binds to C4b; cofactor for cleavage of C4b by factor 1	
CD35 (complement receptor 1)*	Membrane-bound glycoprotein that displaces Bb and binds C3b or displaces C2b and binds C4b; promotes C3b and C4b inactivation by factor 1	
CD55 (decay-accelerating factor [DAF])*	Membrane-bound protein that regulates the formation of C3 convertase by displacing Bb from C3b and C2b from C4b	Deficiency associated with paroxysmal nocturnal hemoglobinuria
CD59 (protectin)*	Prevents formation of the membrane attack complex on host cells	Deficiency causes paroxysmal nocturnal hemoglobinuria
CD46 (membrane cofactor protein, MCP)*	Membrane-bound protein that binds C3b and C4b and promotes their inactivation by factor 1	
Factor H	Plasma protein cofactor for factor 1; displaces Bb and binds C3b in plasma and on host cell surfaces	Deficiency leads to recurrent pyogenic infections, hemolytic-uremic syndrome
Factor I	Plasma protease that inactivates C3b and C4b; requires CR1, factor H, CD46, or C4BP as cofactor	Deficiency results in recurrent bacterial infections

*Present on host but not microbial cell surfaces.
MCP, manocyte chemoattractant protein.

Other proteins that have evolved to inhibit complement activation (Table 23.3) include fluid-phase proteins such as C1 inhibitor and the C3 and C5 convertase inhibitors, C4-binding protein and factor H, membrane-bound proteins such as the C3 and C5 convertase inhibitors, and CD59, a glycolipid that prevents insertion of the MAC into plasma membranes.¹⁷

Complement in disease

Complement deficiencies cause susceptibility not only to bacterial infection but also to autoimmune disease. Patients with specific complement deficiencies are especially prone to SLE; lupus develops in approximately 90% of C1q-null, 75% of C4-null, and up to 30% of C2-null individuals. Why complement deficiency predisposes to autoimmune disease is not entirely clear, but it may result from inefficient clearance of apoptotic cells and immune complexes.¹⁸ Deficiencies of later complement components may have other effects. For example, C5 deficiency results in susceptibility to *Neisseria* infections, thus testifying to the importance of the MAC in responding to these organisms.

Complement activation almost inevitably results in some degree of tissue destruction, as seen in rheumatic diseases such as SLE, RA, vasculitis, and antiphospholipid antibody syndrome. Interest in complement in inflammatory disease has led to the development of pharmacologic complement inhibitors such as eculizumab, a humanized monoclonal anti-C5 antibody approved for paroxysmal nocturnal hemoglobinuria.

Inflammatory conditions also result from hereditary or acquired deficiencies of complement regulatory proteins. For example, deficiency of the C1q inhibitor protein leads to undue complement activity under metabolic stress and the development of intermittent and potentially life-threatening angioedema.

Lipid mediators of inflammation

Given the ubiquity of membrane lipids, it is not surprising that nature has evolved strategies to exploit them for roles in addition to membrane structure. Among the most important roles of membrane lipids is their ability to serve as substrates for the generation of proinflammatory and antiinflammatory mediators.

Arachidonic acid derivatives

Many bioactive lipid mediators are produced through the oxidation of AA, including prostaglandins, leukotrienes, and the more recently recognized lipoxins (Fig. 23.6). AA is a polyunsaturated fatty acid covalently associated with cell membrane phospholipids; phospholipase A₂ catalyzes its release (phospholipase C₂ liberates diacylglycerol [DAG] from membrane triglycerides and can also produce AA via the action of lipase on DAG). In any given cell, the products formed from AA are determined by factors such as the cytokine milieu, specific expression of AA-modifying enzymes, and tissue type.

Cyclooxygenase products

Prostaglandins, so named because they were originally identified in sheep seminal fluid (i.e., from the prostate gland), result from the action of cyclooxygenases (COX-1 or COX-2) on AA. COX enzymes are heterobifunctional: they first incorporate oxygen into AA to form the five-carbon ring common to all prostaglandins and produce the intermediate PGG₂. A second COX reaction reduces PGG₂ to PGH₂ (hence the alternative designation of COXs as PGH synthases). PGH₂ is further converted into stable prostanoids by a variety of specific terminal synthases, which are expressed with some tissue specificity; differentiated cells tend to produce only one prostaglandin type in abundance.

COX-1 and COX-2, encoded on separate chromosomes, are structurally similar and perform the same enzymatic functions, but they are differentially expressed. COX-1 is generally expressed constitutively and is abundant in many tissues and cell types, including the renal collecting tubules, gastric epithelial cells, endothelial cells, macrophages, and platelets. COX-1 products typically participate in homeostasis of the organism and basic physiologic processes (e.g., protection of the gastric mucosa). In contrast, COX-2 is inducible and expressed primarily in inflammatory cells (macrophages, fibroblasts, endothelial cells) in response to stimuli such as IL-1 β , TNF- α , PDGF, and epidermal growth factor.¹⁹ COX-2 products generally contribute to the inflammatory processes that initially drive COX-2 expression. Moreover, COX-2 expression is elevated in many pathologic conditions, including inflammatory arthritis and some neoplasms. On this basis, selective COX-2 inhibitors were developed that were shown to have less gastrointestinal toxicity than nonselective COX inhibitors. However, COX-2 inhibition also appears to convey an increased risk for myocardial infarction, possibly by disturbing the balance between COX-1 and COX-2 products in the vasculature.

The bioactive prostanoids generated from PGH₂ include PGD₂, PGE₂, PGF₂, PGI₂ (prostacyclin), and TXA₂, each of which is produced by the action of one or more specific isomerases (terminal synthases). In contrast, PGJ₂ is derived nonenzymatically via dehydration of PGD₂. Prostaglandins are short-lived and generally act in an autocrine or paracrine manner. The effects of prostaglandins are generally mediated through specific G protein-coupled, seven-transmembrane-domain receptors, which have been classified into five types according to their responsiveness to selective agonists and antagonists. DP, EP, FP, IP, and TP receptors are preferentially engaged by PGD₂, PGE₂, PGF₂, PGI₂, and TXA₂, respectively.

Prostaglandin E₂

PGE₂ is the most common prostanoid and the one most critical for inflammation. PGE₂ induces fever, smooth muscle contraction, and T-cell migration and, along with PGI₂, induces the vasodilation and vascular hyperpermeability of early inflammation.²⁰ Elevated PGE₂ levels have been reported in the serum and synovial fluid of patients with RA and osteoarthritis (OA) and probably contribute to joint damage by promoting osteoclastic bone resorption and inhibiting proteoglycan synthesis. Not all of the effects of PGE₂ are proinflammatory, however; PGE₂ inhibits T-lymphocyte activation and proliferation, downregulates antibody production, and has variable effects on the secretion of MMPs.

PGE₂ is generated from PGH₂ by three different isoforms of PGE synthase (PGES)—cytoplasmic PGES (cPGES), microsomal PGES-1 (mPGES-1), and mPGS-2. Like COX-1, with which it is functionally coupled, cPGES is constitutively and ubiquitously expressed, whereas mPGES-1 is upregulated by proinflammatory stimuli and is functionally coupled with COX-2. mPGES-2 has a less clearly defined role and is linked to both COX isoforms.²¹ In

Fig. 23.6 Arachidonic acid (AA) is liberated from cell membrane phospholipids via phospholipase A_2 activity. Three distinct classes of products—prostanoids, leukotrienes, and lipoxins—may subsequently be generated by the action of distinct enzyme systems. *Prostanoid formation:* cyclooxygenase-1 (COX-1) and COX-2 convert AA sequentially into PGG_2 and PGH_2 . Specific terminal synthases generate all other prostanoid products from PGH_2 , with the exception of PGJ_2 , which is formed from PGD_2 through a dehydration reaction. *Leukotriene formation:* 5-lipoxygenase (5-LO) in concert with 5-lipoxygenase-activating protein (FLAP) act on AA to generate 5-hydroxyeicosapentaenoic acid (5-HPETE) and, subsequently, leukotriene A_4 (LTA_4). LTB_4 is formed from LTA_4 via LTA_4 hydrolase. In contrast, LTC_4 synthase converts LTA_4 into LTC_4 . Subsequently, transpeptidase and dipeptidase convert LTC_4 into LTD_4 and LTD_4 into LTE_4 , respectively. *Lipoxin formation:* Lipoxins are formed through cell-cell interactions during inflammation; two of the several pathways leading to lipoxin formation are shown here. Cells such as airway epithelium produce and release AA-derived 15-S-HETE. 15-S-HETE then diffuses into leukocytes, where it is first converted into 5,6-epoxytetraene by 5-LO and then into LXA_4 or LXB_4 by the action of epoxide hydrolase. Alternatively, when adherent platelets interact with activated leukocytes in the vascular lumen, the LTA_4 released from leukocytes diffuses into platelets, where it is converted to LXA_4 and LXB_4 by 12-LO. In contrast to prostanoids and leukotrienes, lipoxins appear to have largely antiinflammatory effects. Not shown are the aspirin-triggered lipoxins, which form when acted on by aspirin-acetylated COX-2.

experimental systems, COX-2 and mPGES-1 increase in tandem and co-localize to the same subcellular fraction. In human rheumatoid synovial fibroblasts, mPGES-1 expression is induced by IL-1 β and TNF- α and inhibited by dexamethasone.^{22,23} mPGES-1-null mice are resistant to both adjuvant- and collagen-induced arthritis.²⁴ mPGES-1 is therefore an attractive potential therapeutic target.

Other prostaglandins

PGI_2 (prostacyclin) induces vasodilation and inhibits platelet aggregation, qualities that have been exploited in the treatment of pulmonary hypertension. PGD_2 can also produce vasodilation and probably plays a role in allergic inflammation and asthma; on antigenic stimulation, it is released in large amounts by mast cells. In the central nervous system (CNS), PGD_2 regulates sleep. PGF_2 , a powerful uterine constrictor, is not known to participate in inflammatory events.

In contrast, PGJ_2 exerts a number of antiinflammatory effects. Unlike conventional prostaglandins, which signal via cell-surface receptors, PGJ_2 is transported into cells, where it acts on the intranuclear peroxisome proliferator-activating receptor- γ (PPAR- γ). Activated PPAR- γ inhibits the activation of nuclear factor κB (NF- κB), an important transcription factor for proinflammatory genes. In some cell types, PGJ_2 may also directly inhibit NF- κB . *In vitro*, addition of PGJ_2 to human macrophages inhibits the production of IL-1 β , TNF- α , IL-6, IL-12, and inducible nitric oxide synthase (iNOS). In an animal model of arthritis, intraperitoneal administration of PGJ_2 suppressed pannus formation and inflammatory infiltration.²⁵

Thromboxane A_2

TXA_2 is formed from PGH_2 via the enzyme thromboxane synthase. In contrast to prostaglandins, it contains a six-member carbon ring. TXA_2 is a

platelet activator and a potent vasoconstrictor. Platelet TXA_2 production is dependent on COX-1 and unaffected by COX-2 inhibitors, thus suggesting that the prothrombotic effects of selective COX-2 inhibitors may be a consequence of TXA_2 production unopposed by PGI_2 . Although TXA_2 is conventionally thought of as being derived from platelets, thromboxane synthase can be upregulated in other cell types in response to cytokines, and thromboxane production has been implicated in the pathogenesis of murine lupus nephritis.²⁶

Leukotrienes

Leukotrienes are important AA-derived inflammatory mediators as well (see Fig. 23.6 for how they are generated).

LTB_4 is the most important leukotriene in acute inflammatory responses; it activates leukocytes and prolongs their survival. Additionally, LTB_4 is a powerful chemoattractant for neutrophils and macrophages and stimulates leukocyte adhesion to vascular endothelium by upregulating integrin expression.²⁷ LTB_4 is present in high levels in the synovial fluid and sera of RA patients, and LTB_4 antagonism inhibits inflammatory arthritis in several animal models. In a phase 2 clinical trial, however, an LTB_4 receptor antagonist was not efficacious for RA.²⁸

LTC_4 , LTD_4 , and LTE_4 , known as the Cys leukotrienes, are produced principally by eosinophils, basophils, macrophages, and mast cells and have significant biologic effects. They induce vasodilation and increased microvascular permeability; increase bronchoconstriction, wheezing, and mucus secretion; and decrease mucociliary clearance.

Antiinflammatory lipids

Resolution of inflammation depends on an organism's ability to produce antiinflammatory mediators. Among these are AA-derived lipids known as

Fig. 23.7 As shown on the right side of the figure, molecular oxygen is converted to superoxide (O_2^-) by the action of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex. Superoxide dismutase subsequently converts superoxide to hydrogen peroxide (H_2O_2). In the presence of molecular iron, H_2O_2 is spontaneously converted to the hydroxyl radical ($OH^\cdot$), an extremely unstable and reactive oxygen product. Alternatively, reaction of H_2O_2 with molecular chloride is catalyzed by myeloperoxidase in the phagolysosomes of macrophages and neutrophils; the product, hypochlorous acid (HOCl), is an extremely potent antibacterial agent. As shown on the left side of the figure, inducible nitric oxide synthase (iNOS) liberates nitric oxide from the side chain of arginine. Interaction of nitric oxide and superoxide results in the formation of highly reactive peroxynitrites, which can modify and potentially alter the function of a wide range of proteins.

lipoxins (LXs). LXs are formed during the cell-cell interactions that occur during inflammation (see Fig. 23.6).²⁹ The requirement for the presence of two different inflammatory cells for LX formation may be a mechanism for delaying LX production until inflammation has already taken hold, consistent with a role for LX in the resolution phase of inflammation. LXs and their analogues exert multiple antiinflammatory effects, including inhibition of cytokine expression (e.g., IL-1 β , TNF- α , and IL-8), neutrophil chemotaxis/interaction with endothelial and epithelial cells, activation of monocytes, and proliferation of inflammatory cells. LXs also promote macrophage clearance of apoptotic leukocytes.²⁹ *In vivo*, LXs inhibit inflammatory disease in several animal models, including experimental colitis, asthma, and peritonitis³⁰; their role in human inflammation is less well established.

Resolvins and docosatrienes are non-AA-derived lipid molecules that are potent endogenous antiinflammatory mediators. These lipid products are generated from the essential ω -3 polyunsaturated fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA); like LXs, they are produced during the later phases of inflammation and hasten its resolution.³¹ Resolvin E1 significantly inhibits leukocyte infiltration in murine models of inflammation and protects against the development of sulfonic acid-induced colitis.^{32,33} A recent systematic review demonstrated a consistent (albeit modest) benefit of EPA and DHA supplementation in RA.³⁴

Vasoactive amines

Low-molecular-weight amines that are important inflammatory mediators include histamine and serotonin. Histamine is the decarboxylation product of the amino acid histidine. It is released from mast cells and basophils during cell stimulation, most particularly after surface IgE binding and cross-linking of Fc ϵ receptors. Histamine interacts with its receptors to promote immediate hypersensitivity reactions, including vasodilation and enhanced permeability of postcapillary venules.

In addition to its role as a neurotransmitter, serotonin is stored in the dense body granules of platelets. Serotonin is a vasoconstrictor and also enhances microvascular permeability. In addition, serotonin promotes fibrosis by enhancing collagen synthesis by fibroblasts and may therefore play a role in periaortitis-associated retroperitoneal fibrosis.

Reactive oxygen species and nitric oxide

ROSs and nitric oxide (NO) are small molecules containing unpaired electrons that are highly reactive with cellular components. Inappropriate activation of macrophages and neutrophils during acute and chronic inflammation can lead to the release of ROSs into the extracellular milieu and result in damage to extracellular and cellular components. The major ROSs formed by cells are, in descending order of stability, superoxide,

hydrogen peroxide, and the hydroxyl radical (Fig. 23.7). The hydroxyl radical has a half-life of less than 10^{-6} second and is probably responsible for much of the havoc wreaked by oxidative intermediates.³⁵

Phagocytes generate ROSs in large amounts in the form of superoxide via phagocyte oxidases (PHOXs), which include an NADPH oxidase complex. (NADPH oxidases are also found in other cells, where they are termed NOXs [nonphagocytic oxidases].)³⁶ In contrast to the ROSs generated by phagocytes for inflammation and host defense, ROSs produced by NOX tend to influence homeostatic cellular events, including cell proliferation and apoptosis.³⁶ The proinflammatory transcription factors activator protein 1 and NF- κ B were among the first intracellular complexes discovered to be substrates for ROS signaling.³⁷ These spur the production of dozens of proinflammatory mediators, including collagenase, IL-1 β , and TNF- α , as well as lead to increased adhesion molecule expression on endothelium and leukocytes.

Nitric oxide

NO is synthesized via oxidation of arginine by one of three distinct NOS isoforms (see Fig. 23.7). The neuronal (nNOS) and endothelial (eNOS) isoforms are constitutively expressed, with activity regulated by intracellular calcium levels and the calcium-binding protein calmodulin. In contrast, the inducible (iNOS) isoform is induced by stimuli such as LPS, IL-1 β , TNF- α , and IFN- α ; its activation leads to sustained generation of NO.³⁸ NO production plays vital roles in regulating physiologic processes, host defense, inflammation, and immunity. Its proinflammatory effects include vasodilation, edema, cytotoxicity, and mediation of cytokine-dependent processes that lead to tissue destruction. NO-dependent tissue injury has been implicated in a variety of rheumatic diseases, including SLE, RA, and OA. Conversely, the production of NO by eNOS may serve a protective, or antiinflammatory, function by preventing adhesion and the release of oxidants by activated neutrophils in the microvasculature.³⁹

NO, a gaseous free radical, is labile (half-life <5 seconds) and in the presence of oxygen is rapidly metabolized to nitrate and nitrite.⁴⁰ Given the short half-life of NO itself, its biologic activity in tissues is usually determined by its alteration of target molecules. One important reaction of NO is with free thiols to form S-nitrosothiol compounds. S-nitrosothiol derivatives, formed both extracellularly and intracellularly, are significantly more stable (half-life >2 hours) and retain NO-like vasodilating properties with less cytotoxicity.⁴¹ The reaction of NO with superoxide anion yields peroxynitrite, a highly toxic free radical that nitrosylates proteins and thereby leads to the accumulation of injurious intracellular oxidants and DNA damage (see Fig. 23.7).

NO and its derivatives play complex roles in immunoregulation. Low NO levels promote lymphocyte activation and proliferation, whereas high concentrations suppress APC activity and T-cell proliferation.^{42,43} There is

Fig. 23.8 Joint denervation prevents arthritis. Sensory denervation of the rat knee joint prevents the development of arthritis. (a) Normal rat knee 24 hours after the injection of carrageenan. Note the intense inflammation. (b) Denervated rat knee 24 hours after the injection of carrageenan. (Reproduced with permission from the BMJ Publishing Group.)

evidence that NO exerts different effects on discrete subpopulations of T cells: inhibition of secretion of IL-2 by murine type 1 helper T (Th1) cells and an increase in the secretion of IL-4 by Th2 cells. At high concentrations, NO promotes apoptosis in macrophages, CD4+CD8+ thymocytes, and chondrocytes.^{44,45} At lower concentrations (<1 mM), NO inhibits the apoptosis of hepatocytes, B lymphocytes, and eosinophils via the inhibition of caspases.⁴⁶

Although excessive NO production is generally associated with tissue injury, it is important to note that NO constitutively produced by endothelium is thought to play a protective role in the microvasculature. This protection is afforded by the capacity of NO to inhibit platelet and neutrophil adhesion to endothelial monolayers, as well as to inhibit superoxide anion production by leukocytes.⁴⁷

Nitric oxide in rheumatic diseases

NO has been implicated in the pathogenesis of lupus in murine models.⁴⁸ Splenic and renal tissues from MRL/lpr mice demonstrate increased iNOS mRNA expression and increased amounts of material immunoreactive for iNOS. Administration of NG-monomethyl-L-arginine (L-NMMA), an NOS inhibitor, prevents the development of glomerulonephritis and reduces inflammatory arthritis in this model.⁴⁸ In human SLE, serum nitrite is elevated during active disease, and levels correlate with disease activity and autoantibody titers.^{49,50}

The importance of NO in experimental arthritis models is also well documented. Adjuvant-induced arthritis is suppressed by the NOS inhibitor L-NMMA.⁵¹ Elevations of NO and amelioration of disease by nonselective NOS inhibitors have also been demonstrated in collagen-induced arthritis and streptococcal cell wall arthritis.⁵¹⁻⁵³ Inhibition of NO production also attenuates OA in animal models.^{54,55} In human arthritis, increased nitrite levels have been demonstrated within the joint fluid of patients with OA and RA.^{56,57} iNOS expression has been demonstrated in both RA and OA synoviocytes and chondrocytes.⁵⁸ St. Clair and colleagues⁵⁹ reported increased expression of iNOS in blood mononuclear cells in RA patients. In these studies the degree of nitrite production by peripheral mononuclear cells *ex vivo* correlated with disease activity, and this group demonstrated that the increased expression of iNOS and iNOS enzyme activity by peripheral blood mononuclear cells was reduced with anti-TNF therapy. Changes in NOS activity after treatment correlated significantly with changes in the number of tender joints.

THE NERVOUS SYSTEM IN INFLAMMATION

The immune and nervous systems are in constant communication, and the inflammatory response involves a complex bidirectional interaction between the two such that the nervous and immune systems together constitute a unified defense mechanism against internal and external threats. The nervous system registers inflammation in the periphery via sensory nerves and directs the immune system through a variety of messengers ranging from autonomic neurotransmitters (e.g., acetylcholine) to peripherally synthesized neuropeptides such as substance P (SP), which can be either

proinflammatory or antiinflammatory. The CNS also controls inflammatory responses through the release of neuroendocrine hormones such as melanocyte-stimulating hormone (MSH) and corticotropin-releasing factor (CRF), which dampen inflammation. Conversely, the immune system regulates the CNS through the release of cytokines, growth factors, and other mediators; release of cytokines in the periphery, for instance, can induce the hypothalamic-pituitary-adrenal axis to release glucocorticoids.

Both clinical and experimental evidence support the finding that the peripheral nervous system modulates inflammatory arthritis. As early as 1965 it was observed that peripheral nerve transection attenuates distal inflammation in rats with adjuvant-induced arthritis.⁶⁰ Carrageenan-induced joint inflammation is also inhibited by joint denervation (Fig. 23.8). Clinically, hemiparetic patients in whom RA later develops are largely spared from disease on the paralyzed side. That RA is characteristically symmetric (indicating cross-spinal reflexes) and predominantly distal (where dense sensory innervation occurs) also suggests possible CNS involvement.

Joint innervation

Joints are heavily innervated with sensory nerve branches terminating in the joint capsule, synovium, entheses, subchondral bone, and periosteum. Normal synovial tissue is richly innervated with both sensory and sympathetic nerves. Type C sensory nerve fibers containing neuropeptides such as SP or calcitonin gene-related peptide (CGRP) are present in the synovial lining and sublining tissue and in the vascularized peripheral parts of the joint menisci. Mast cells and afferent nerve terminals are frequently observed in all parts of the normal synovium.

Autonomic influences on inflammation

The autonomic nervous system is hard-wired into the immune system; parasympathetic branches from the vagal nerve and sympathetic nerve fibers synapse on the major organs of immunity, including the spleen, lymph nodes, thymus, bone marrow, and the gut's mucosa-associated lymphoid tissue. Thus, there exists a dense established network that provides direct lines of communication between the immune and autonomic nervous systems, which permits rapid and robust responses when stimulated.

The parasympathetic nervous system: an antiinflammatory pathway

Leukocyte-derived inflammatory mediators activate parasympathetic sensory nerve fibers that ascend in the vagus nerve. Afferent parasympathetic signals trigger efferent parasympathetic responses in the nucleus tractus solitarius that result in the release of acetylcholine, which has potent local antiinflammatory effects on both macrophages and endothelium.⁶¹

In vitro, acetylcholine inhibits production of TNF- α , IL-1 β , and IL-18 by macrophages while permitting synthesis of the largely antiinflammatory cytokine IL-10. Acetylcholine also inhibits the release of a recently recognized inflammatory mediator, high-mobility group box-1 (HMGB-1), by macrophages exposed to TNF- α .⁶² The antiinflammatory effects of acetylcholine appear to be due to engagement of $\alpha 7$ nicotinic receptors

TABLE 23.4
Inflammatory effects of selected neuropeptides

Neuropeptide	Where produced (outside the CNS)	Effects on inflammation	Evidence for involvement in arthritis
Substance P (SP; neurokinin)	C-type nerve fibers Lymphocytes Macrophages Eosinophils	Arteriole vasodilation Increased microvascular permeability Chemoattraction and activation of macrophages, polymorphonuclear neutrophils, lymphocytes, and eosinophils Mast cell degranulation	Elevated SP in synovial fluid of RA joints RA synovial fibroblasts (RASFs) overexpress SP receptor (NK-1R) Stimulates RASFs to proliferate and secrete inflammatory products
Calcitonin gene-related peptide (CGRP)	C-type nerve fibers	Potent arteriole and venous vasodilator	CGRP overexpressed in entheses of animals with adjuvant-induced arthritis Elevated CGRP levels in synovial tissue from OA joints
Neuropeptide Y (NPY)	Sympathetic nerve fibers	May favor Th2 response: inhibits IFN- γ and stimulates IL-4 production in lymphocytes	RA synovium has paucity of NPY-containing nerve fibers
Vasoactive intestinal peptide	Peripheral nerves Mast cells Lymphocytes Polymorphonuclear neutrophils Macrophages	Antiinflammatory peptide Inhibits chemotaxis and activation of macrophages and T cells Stimulates production of IL-4, IL-10, and IL-1ra	Therapeutic in collagen-induced arthritis

CNS, central nervous system; IFN- γ , interferon- γ ; IL-1ra, interleukin-1 receptor antagonist; OA, osteoarthritis; RA, rheumatoid arthritis; Th2, type 2 helper T cell.

on macrophages, which results in decreased synthesis of TNF- α .⁶³ This intimate connection between the nervous and immune systems can thus profoundly modulate the inflammatory response. The selective cholinergic agonist nicotine improves survival in experimental sepsis and has been associated with improvement of ulcerative colitis.^{40,62} Stimulation of the vagal nerve suppresses carrageenan-induced arthritis and endotoxemic shock. These findings may lead to newer and safer cholinergic agonists that may be used to treat inflammatory disease.

Sympathetic nervous system

Sympathetic nerve fibers release norepinephrine, which acts on target cells, including most immune cell types, by engaging α_1 -, α_2 -, and β -adrenoreceptors. The effects of the sympathetic nervous system on immunity and inflammation are mixed and vary with the cell and clinical context. For instance, the effects of norepinephrine on macrophages depend on which receptors are being expressed and engaged. Ligation of macrophage β -adrenoreceptors inhibits TNF- α secretion, whereas α_2 -receptor engagement induces the release of TNF- α and binding of the α_1 -receptor stimulates complement production.⁶⁴ In addition to inhibiting macrophage function, activated β -adrenergic receptors also inhibit neutrophil and NK cell function. β -Adrenoreceptor ligation can also cause a Th2 shift, largely by increasing IL-10 production.⁶⁴ Furthermore, norepinephrine is often released in sync with release of corticotropin, and glucocorticoids are potentiated in the presence of norepinephrine. On the other hand, stimulation of β -adrenoreceptors also drives IL-8 secretion by monocytes, and localized, neurogenic inflammation is promoted by the activation of β -adrenoreceptors.⁶⁴ In contrast to the mixed effect of β -adrenoreceptors on macrophages, the function of α -adrenergic receptors on immune cells is largely proinflammatory.

Consistent with these somewhat confusing *in vitro* observations, animal studies have shown that disrupting sympathetic nervous system signaling can either worsen or improve inflammatory disease, depending on context. Sympathectomy ameliorates early, but exacerbates late inflammation in collagen-induced arthritis. In contrast, β -adrenergic agonists improve late-stage experimental arthritis. The distinct proinflammatory and antiinflammatory effects of norepinephrine may in part relate to dose because much higher concentrations of norepinephrine are required to activate the β -adrenergic receptor; a low density of sympathetic fibers may therefore dictate a primarily α -adrenergic response in arthritic joints. In this context, it is interesting to note that RA patients have a relative paucity of sympathetic nerve fibers in the synovium.⁶⁵ Moreover, RA CD8+ T cells have fewer β -adrenoreceptors, thus suggesting that they may be resistant to inhibition by norepinephrine.⁶⁶ In one very small 14-day randomized clinical trial in the 1980s, guanethidine was used to achieve regional sympathetic blockade in a group of 24 RA patients, which resulted in decreased symptoms and improved grip strength.⁶⁷

Neuroendocrine mechanisms

The hypothalamus continuously receives data about the body's environment and, in response to stress signals such as IL-1 β , releases CRF. CRF activates the pituitary to secrete adrenocorticotrophic hormone (ACTH), which in turn stimulates the adrenal glands to produce and secrete glucocorticoids, potent endogenous antiinflammatory immunomodulators. MSH, which derives from the same precursor as ACTH, is also secreted by the pituitary gland and can suppress inflammation. Systemic administration of MSH improves inflammatory arthritis, experimental colitis, and experimental allergic encephalomyelitis.⁶⁸ Recent studies of crystal-induced arthritis suggest that the antiinflammatory effects of MSH are mediated through engagement of a specific receptor, MSH-R3.

Peripheral nervous system

Peripheral sensory nerves, on stimulation by noxious agents such as bradykinin, histamine, or inflammatory cytokines such as IL-1 (nerves can also directly respond to pathogen-derived factors via membrane-bound pattern recognition receptors),⁶⁹ not only transmit pain signaling but also secrete inflammatory mediators known as neuropeptides. Neuropeptides are neurotransmitters that are generally thought to mediate neuron-to-neuron communication, but they also act on (and are produced by) cells outside the nervous system, such as macrophages, dendritic cells, and lymphocytes. Neuropeptides have pleiotropic effects and can both contribute to and help resolve inflammation. Early in the acute inflammatory response, neuropeptides trigger a number of critical events, including arteriolar vasodilation, increased microvascular permeability, and leukocyte recruitment (Table 23.4). In recognition of this role of neuropeptides, the edema, warmth, and redness seen in early inflammatory lesions are sometimes collectively referred to as neurogenic inflammation.

Conversely, neuropeptides may hasten the resolution of inflammation by induction of regulatory T cells.⁷⁰

Neuropeptides

Substance P

SP was first discovered and purified in powder form (hence its name "substance powder") in 1931. It is widely distributed throughout the peripheral and central nervous systems, where it functions largely as a transmitter of pain signaling. Unmyelinated C-type nerve fibers release SP in response to noxious stimuli, and a variety of proinflammatory effects are produced by acting on target cells through binding and activation of the NK-1 receptor (NK-1R). SP ligation of NK-1R on postcapillary endothelium increases microvascular permeability and causes edema; it also induces vasodilation in arterioles.⁷¹ SP acts as a chemoattractant and activator for macrophages, lymphocytes, neutrophils, and eosinophils. Mast cells also possess NK-1R and degranulate in response to SP, which leads to the release of histamine

and serotonin. Lymphocytes proliferate and differentiate when stimulated with SP, and some leukocytes (e.g., lymphocytes, macrophages, and eosinophils) are themselves capable of SP expression.⁷²

Substantial evidence supports a role for SP in inflammatory arthritis. In animal models, more severely affected joints have higher levels of SP.⁷² Exogenous SP directly infused into joints exacerbates experimental arthritis, whereas neural depletion of SP by pretreatment with capsaicin ameliorates joint inflammation.^{73,74} In a mouse model of adjuvant-induced arthritis, NK-1R knockout mice experienced less joint swelling and plasma extravasation.⁷⁵

Increased levels of SP are found in a number of human inflammatory diseases, including RA, inflammatory bowel disease, and asthma.⁷⁰ *In vitro*, RA synovial fibroblasts (RASFs) respond to nanomolar concentrations of SP by releasing PGE₂ and MMP-1 and proliferating.⁷⁶ At these same concentrations, SP also stimulates the production of IL-1, TNF- α , and IL-6 in peripheral whole blood from RA patients. Increased levels of both SP and NK-1R are found in the synovial fluid of RA joints, and RASFs overexpress NK-1R mRNA. NK-1R antagonists have not yet been studied for the treatment of RA, but anti-TNF therapies reduce serum levels of SP in patients with RA.⁷⁷

Calcitonin gene-related protein

CGRP, an alternative splice product of calcitonin, is a widely distributed neuropeptide that is released primarily from small peripheral sensory nerves. It acts on the complex of the G protein-coupled calcitonin receptor-like receptor (CLR), which is expressed by smooth muscle, endothelial cells, macrophages, and lymphocytes. CGRP is co-localized and released with SP in afferent nerves and is a potent arterial and venous vasodilator, particularly in the microvasculature.⁷⁸

It is overexpressed at the nerve endings of animals with adjuvant-induced arthritis and in sensory neurons in rats with collagen-induced arthritis.^{72,79} Synovial tissue from OA joints also contains nerve endings with high

concentrations of both SP and CGRP,⁸⁰ consistent with a role in inflammation. However, CGRP may be a mixed proinflammatory and antiinflammatory agent because it inhibits T-cell and pre-B-cell differentiation, macrophage antigen presentation, IL-1 production,⁷⁸ and RASF activity *in vitro*.⁸¹

Neuropeptide Y

Neuropeptide Y is a tachykinin released from sympathetic nerve endings. Unlike SP, neuropeptide Y exerts both proinflammatory and antiinflammatory effects. Neuropeptide Y inhibits IFN- γ and stimulates IL-4 production in rat lymphocytes,⁸² thus suggesting that it may favor Th2 responses and therefore modify Th1-predominant diseases such as RA and multiple sclerosis. Neuropeptide Y ameliorates disease severity in experimental allergic encephalomyelitis (the animal model of multiple sclerosis) but has not yet been tested in models of inflammatory arthritis.⁸³ The spinal fluid of patients with multiple sclerosis shows depressed levels of neuropeptide Y, and the synovium of RA patients has a paucity of neuropeptide Y-containing nerve fibers, which may help maintain the Th1 response.

Vasoactive intestinal peptide

Vasoactive intestinal peptide (VIP) is a neuropeptide synthesized and released by immune cells, as well as by nerve endings that synapse on central and peripheral lymphoid organs. VIP is a potent antiinflammatory peptide that inhibits chemotaxis and activation of macrophages and T cells. Consequently, it inhibits the production of TNF- α , IFN- γ , IL-6, and IL-12 and stimulates production of the antiinflammatory cytokines IL-10 and IL-Ra.⁸⁴ VIP may additionally shift T cells to a Th2 phenotype because it increases IL-4 production, and it may promote regulatory T-cell production. VIP has been shown to be therapeutic in several inflammatory models, including sulfonic acid-induced colitis, sepsis, and collagen-induced arthritis, and a recent clinical trial demonstrated immunoregulatory effects in a cohort of patients with pulmonary sarcoidosis.^{84,85}

Scientific basis of pain

■ HANS-GEORG SCHAIBLE

- Nociception is the encoding and processing of noxious stimuli in the nervous system; the subjective sensation pain is evoked by nociception and influenced by psychological and social factors.
- Clinically relevant pain is classified as nociceptive when tissue is inflamed or damaged or as neuropathic when nerve fibers or nerve cells are affected.
- Peripheral nociceptors are slowly conducting, thinly myelinated or unmyelinated nerve fibers that respond to tissue-damaging mechanical, thermal, and chemical stimuli.
- The central nociceptive system consists of neurons in the spinal cord, brain stem, thalamus, and cortical areas that process noxious stimuli; the conscious pain sensation with its sensory-discriminative and affective components is generated at the thalamocortical level.
- During inflammation, peripheral nociceptors are sensitized to mechanical or thermal stimuli (or to both) by inflammatory mediators (peripheral sensitization).
- Damaged nerve fibers may show action potentials that are evoked at the site of the lesion and in neuronal cell bodies (ectopic discharges).
- Peripheral sensitization and ectopic discharges may induce a state of hyperexcitability in the central nociceptive system (central sensitization) that increases the gain of central nociceptive processing.
- Nerve fibers originating in the brain stem can enhance or inhibit spinal nociceptive processing (descending facilitation or inhibition).

NOCICEPTION AND PAIN

Pain is an unpleasant sensory and emotional experience that is evoked by actual or potential noxious (i.e., tissue-damaging) stimuli or by tissue injury or is described in such terms. Because pain is a subjective experience, it cannot be measured objectively. *Nociception* is the encoding and processing of noxious stimuli in the nervous system and can be measured objectively (e.g., with electrophysiologic recordings). Under normal conditions the relationship between nociception and pain is relatively precise and predictable. A stimulus that is noxious will usually evoke a subjective pain response. However, under clinically relevant conditions the relationship between nociception and pain may not be strict, particularly when the pain is chronic (see later).

Neurons in the peripheral and central nociceptive system that encode noxious stimuli form the nociceptive system. A simplified scheme of the nociceptive system is shown in [Figure 24.1](#). Peripheral nociceptive neurons (nociceptors) innervate the skin, deep tissue, and most visceral organs. They encode noxious stimuli applied to the tissue. The central nociceptive system consists of sensory nociceptive neurons in the spinal cord, spinal reflex pathways, and ascending tracts that activate the brain stem and supraspinal structures in the thalamus and cortex. Corticothalamic networks produce the conscious pain response.^{1,2}

Types of pain

Application of a noxious stimulus to *normal* tissue elicits *acute physiologic nociceptive pain*. This pain protects tissue from being damaged further because withdrawal reflexes are usually elicited. Inflammation or injury causes *pathophysiologic nociceptive pain*. It may appear as spontaneous

(resting) pain, hyperalgesia, allodynia, or any combination of these types of pain. *Hyperalgesia* is higher pain intensity felt on noxious heat stimulation (thermal hyperalgesia) or noxious mechanical stimulation (mechanical hyperalgesia). *Allodynia* is pain elicited by stimuli that are normally below the pain threshold.¹

Whereas *nociceptive pain* is elicited by noxious stimulation of the sensory endings of nociceptors in tissues, *neuropathic pain* is caused by injury or disease of nociceptive neurons in the peripheral or central nervous system. This pain does not primarily signal tissue damage. It often has an abnormal burning or electrical character and can be persistent or episodic (e.g., trigeminal neuralgia). It may be combined with hyperalgesia and allodynia. Thus, even touching the skin with a soft brush can cause intense pain. Causes of neuropathic pain include nerve or plexus damage, metabolic diseases such as diabetes mellitus, and herpes zoster. Damage to central pain-processing neurons (e.g., in the thalamus) can cause central pain.^{1,3}

Usually, pain is called “chronic” when it lasts longer than 6 months. Chronic pain may result from persistent nociception (with a chronic disease), but it is often significantly influenced by psychological and social factors. It can be accompanied by neuroendocrine dysregulation, fatigue, dysphoria, and impaired physical and even mental performance.⁴

THE PERIPHERAL BASIS OF PAIN

Structure and dual function of peripheral nociceptors

Nociceptors are sensory neurons with thinly myelinated A δ - or unmyelinated C-fiber axons. The cell bodies of nociceptors are located in the dorsal root ganglia. Their peripheral branches form sensory endings (“free nerve endings”) in the innervated tissue, and their central branches terminate in the dorsal horn of the spinal cord or in the brain stem, where they activate synaptically nociceptive dorsal horn neurons (see [Fig. 24.1](#)).⁵

Many nociceptors have a dual function. They encode noxious stimuli and transmit this information to the spinal cord (sensory function). In addition, they transport neuropeptides such as substance P and calcitonin gene-related peptide (CGRP) from the cell body to the periphery and release these mediators in the tissue on stimulation. There, these neuropeptides induce vasodilatation, plasma extravasation, attraction of macrophages, degranulation of mast cells, or other processes that elicit *neurogenic inflammation*. Such neurogenic components contribute significantly to many inflammatory diseases.⁶

Sensory function of nociceptors

Most nociceptors respond to noxious *mechanical* stimuli (painful pressure, squeezing or cutting the tissue), noxious *thermal* stimuli (heat or extreme cold), and *chemical* stimuli and are therefore called *polymodal*. Noxious stimuli evoke a sensory potential in the sensory ending (transduction). When the depolarization is sufficiently strong, action potentials are triggered and conducted by the axon to the spinal cord or the brain stem ([Fig. 24.2](#)).⁵

In joints, nociceptors innervate mainly the fibrous capsule, ligaments, adipose tissue, menisci, and the synovial layer. The cartilage is normally not innervated. A typical joint nociceptor is activated by strong pressure on the joint (e.g., hitting the joint) and by noxious movements (i.e., painful rotation against resistance of the tissue). It is not usually activated by movements and positions in the working range.⁷ Nociceptors in muscle are located in the muscle belly and in the tendon. They respond to noxious (painful) compression of the muscle, they may be activated by muscle

SCHEME OF THE NOCICEPTIVE SYSTEM WITH NOCICEPTIVE FREE NERVE ENDINGS IN THE PERIPHERAL TISSUE, AFFERENT NERVE FIBERS AND THEIR SYNAPSES IN THE DORSAL HORN OF THE SPINAL CORD, AND ASCENDING TRACTS

Fig. 24.1 The nociceptive system consists of nociceptive free nerve endings in peripheral tissue, afferent nerve fibers, and their synapses in the dorsal horn of the spinal cord. From there the medial and lateral spinothalamic tracts ascend to the medial and lateral thalamus, and interneurons project into motor and sympathetic reflex pathways. Note: Other ascending pathways such as the spinoreticular tract and dorsal column pathways are not displayed.

contraction under ischemic conditions, and some of them are activated by noxious thermal stimuli. Normally, they do not respond to innocuous pressure and to contractions of the muscle.⁵ Cutaneous nociceptors respond to noxious heat (in the range of 42°C to higher than 50°C), and they encode noxious mechanical stimuli such as squeezing.⁵ Visceral nociceptors respond to a variety of mechanical, thermal, and chemical stimuli.⁵

Notably, not all nociceptors are polymodal. An important group of nociceptors is relatively mechanoinensitive and, in the skin, heat insensitive. Because these nociceptors do not respond to noxious stimuli applied to normal tissue, they were initially called *mechanoinensitive* or *silent* nociceptors.^{1,7} These nociceptors are “recruited” during inflammation (see later).

With repetitive or strong noxious stimulation of the tissue, nociceptors are often *sensitized* to stimuli. The excitation threshold of polymodal nociceptors drops such that even light, normally innocuous stimuli activate the fibers, and silent nociceptors become excitable by innocuous and noxious stimuli.^{1,7} This *peripheral sensitization* produces enhanced input to the spinal cord and induces *central sensitization* there (Fig. 24.3). Both peripheral sensitization and central sensitization cause *primary hyperalgesia* and *allodynia* at the site of inflammation. In addition, central sensitization causes *secondary hyperalgesia*, or enhanced pain sensitivity in healthy tissue surrounding the site of inflammation (Fig. 24.4).

Molecular mechanisms of peripheral stimulus transduction and peripheral sensitization

The sensory endings of nociceptors express ion channels and membrane receptors that transduce the mechanical, thermal, and chemical stimuli into a sensory potential (see Fig. 24.2). Some sensory molecules have been identified.⁸ The best known is transient receptor potential vanilloid 1 (TRPV1), a ligand-gated ion channel that is expressed in nociceptors but not in other peripheral neurons. On opening, cations, in particular, Ca^{2+} , flow into the cell and depolarize it. TRPV1 is opened by temperatures higher than 43°C, which are felt as painful heat by humans; by chemicals that elicit burning pain, such as capsaicin and ethanol applied to a wound; and by low pH (less than 5.9), which occurs in inflamed tissue. TRPV1 is activated by metabolites of arachidonic acid produced by lipoxygenases such as 12-hydroperoxyeicosatetraenoic acid (12-HPETE) and by endocannabinoids such as anandamide and N-arachidonoyl-dopamine (NADA). Furthermore, TRPV1 is sensitized via second messengers by the inflammatory mediators bradykinin, prostaglandin E_2 (PGE_2), extracellular adenosine triphosphate, glutamate, proteases, cytokines, and nerve growth factor (NGF).

Fig. 24.2 Sketch of the enlarged sensory ending of a nociceptor in tissue. At the bottom is shown ion channels for the transduction of thermal, mechanical, and chemical stimuli (they produce a sensory potential) and voltage-gated ion channels (opening of Na^+ channels produces action potentials). At the top and the left side are displayed metabotropic receptors for chemical mediators. ASIC, acid-sensing ion channel; TRP, transient receptor potential; TTX, tetrodotoxin. Classic mediators are bradykinin, prostaglandin E_2 , and others. (From Schaible H-G, Ebersberger A, Natura G. Update on peripheral mechanisms of pain: beyond prostaglandins and cytokines. *Arthritis Res Ther* 2011;13:210.)

Thus, TRPV1 is one transducer of noxious heat, and it is the crucial ion channel for inflammatory *thermal hyperalgesia*.⁸

Other TRP channels such as TRPV2, TRPV3, TRPV4, TRPM8, and TRPA1 are also expressed in a proportion of primary sensory neurons. Some of them are coexpressed with TRPV1, whereas others are expressed in non-nociceptive neurons. For example, TRPM8 is opened by temperatures that are felt to be cool—hence TRPM8 is assumed to be the transducer in non-nociceptive cold fibers. In general, the role of these other TRP channels is less clear. TRP ion channels such as TRPA1 and TRPV4 may also be involved in the transduction of mechanical stimuli and in mechanical hyperalgesia, which is more important than thermal hyperalgesia. However, the ionic basis of mechanonociception is poorly understood.⁸

When the sensory ending is sufficiently depolarized through the ion channels of transduction, voltage-gated Na^+ channels are opened and action potentials are triggered (see Fig. 24.2). Nociceptive sensory neurons express mainly the sodium channel types $\text{Na}_v1.7$, $\text{Na}_v1.8$, and $\text{Na}_v1.9$, whereas large-sized nonnociceptive neurons express mainly $\text{Na}_v1.1$, $\text{Na}_v1.6$, $\text{Na}_v1.7$, and some $\text{Na}_v1.8$. $\text{Na}_v1.7$ and $\text{Na}_v1.8$ channels are directly involved in generation of the action potential, and $\text{Na}_v1.9$ influences the threshold for action

potentials. These channels can be upregulated or downregulated by second messenger pathways involving protein kinase A, protein kinase C, sphingomyelinase, calmodulin, and p38 mitogen-activated protein kinase. The excitability of neurons may also be controlled by K^+ channels (e.g., of the KCNQ family) and Ca^{2+} channels. Excitability is increased when voltage-gated K^+ channels are closed (this evokes sustained depolarization of neurons) or when Ca^{2+} flows into the neuron through voltage-gated T-type channels.⁹

In addition, nociceptors express receptors for inflammatory mediators in the membrane (see Fig. 24.2); Box 24.1 shows which particular mediator receptors are expressed in subgroups of sensory neurons.^{9,10} Inflammatory mediators sensitize nociceptors to mechanical and thermal stimuli. Ligand binding of these membrane receptors activates second messenger systems, which then render both transduction molecules and voltage-gated ion channels more excitable (e.g., by phosphorylation). For instance, PGE_2 acts on G protein-coupled EP receptors to increase cyclic adenosine monophosphate. This activates protein kinase A, which finally leads to phosphorylation of TRPV1 and voltage-gated Na^+ channels. In the long term, some mediators may also regulate the expression of such ion channels in the membrane. In addition, sensory nerve endings possess Toll-like receptors that signal molecular patterns of infectious agents, thus indicating an important role of nociceptive nerve fibers in the context of innate immunity.

“Classic inflammatory mediators” such as bradykinin and prostaglandins activate or sensitize neurons within minutes, and the effects are quite short-lived (minutes only). By contrast, injection of proinflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor- α (TNF- α) into the joint leads to slowly developing, but persistent sensitization of nociceptive afferents (i.e., an increase in the number of action potentials in response to a stimulus) that lasts at least several hours. In addition, cytokines regulate the expression of molecules of nociception (e.g., TNF- α upregulates TRPV1 receptors).¹¹ These effects of cytokines can be blocked by anticytokine

Fig. 24.3 Spinal cord hyperexcitability (central sensitization) can result from both peripheral sensitization and ectopic pathologic discharges in the afferent nerve fiber. The brain stem (also rendered hyperexcitable) provides feedback to the spinal cord that is either inhibitory or facilitatory.

BOX 24.1 RECEPTORS FOR MEDIATORS IN SUBGROUPS OF SENSORY NEURONS

Ionotropic receptors for

- Adenosine triphosphate (ATP), H^+ (acid-sensitive ion channels [ASICs]), glutamate (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA], kainate, *N*-methyl-D-aspartate [NMDA] receptors), acetylcholine (nicotinic receptors), serotonin (5-HT₃)

Metabotropic receptors for

- Acetylcholine, epinephrine, serotonin, dopamine, glutamate, γ -aminobenzoic acid, ATP
- Prostanoids (prostaglandins E_2 and I_2), bradykinin, histamine, adenosine, endothelin
- Neuropeptides (e.g., substance P, calcitonin gene-related peptide, somatostatin, opioids)
- Proteases (protease-activated receptors PAR1 and PAR2)

Fig. 24.4 Central sensitization. (a) Regions of primary and secondary hyperalgesia produced by peripheral and central sensitization. (b) Mechanisms of spinal sensitization: (1) enhanced release of transmitters from sensitized nociceptors, (2) enhanced excitability of postsynaptic neurons, (3) suprathreshold synaptic activation by afferents from remote regions (in the normal, nonsensitized state insufficient), and (4) spinal release of mediators from glial cells and other cells.

therapy with biologic agents, and it is expected that this also inhibits release of proinflammatory substance P and other neuropeptides.

NGF is an essential neurotrophin for the development of sensory nerve fibers. In adults, a large proportion of sensory nerve fibers remain dependent on the trophic effect of NGF. These neurons express tyrosine kinase receptor A (TrkA) (specific for NGF), and NGF is required for their structural and functional integrity. However, substantial amounts of NGF are also produced at inflammatory sites, where NGF acts as an inflammatory mediator. It enhances currents through TRPV1 channels and reduces the threshold for thermal excitation. Long-term exposure to NGF increases the expression of TRPV1, bradykinin, and P2X receptors and Na⁺ channels, as well as the synthesis of substance P and CGRP. In addition, NGF stimulates inflammatory cells to release inflammatory compounds. Thus, NGF is a key molecule in nociceptor biology, and neutralization of it has proved to be highly analgesic in humans.⁹

Nociceptors also express receptors for neuropeptides. Substance P and CGRP sensitize part of the neurons, whereas opioid peptides and somatostatin inhibit the neurons. Thus, actual receptor sensitivity is due to a balance between excitatory and inhibitory influences.⁹

Peripheral mechanisms of neuropathic pain

In healthy sensory nerve fibers, action potentials are generated in the sensory endings on stimulation of the innervated tissue. By contrast, damaged nerve fibers often show pathologic *ectopic discharges*—action potentials generated at the site of nerve injury or in the cell bodies of impaired fibers in dorsal root ganglia. Neuropathic pain may also be generated by intact nerve fibers in the vicinity of injured nerve fibers that are affected by the process of wallerian degeneration.³ Pathologic discharges may cause a state of central sensitization (see Fig. 24.3).

Different mechanisms can produce ectopic discharges. First, after nerve injury, changes in the expression of Na⁺ channels may alter the membrane properties of the neuron such that rapid firing rates (bursting ectopic discharges) are favored. Changes in the expression of K⁺ channels in neurons have also been shown. Second, injured axons of primary sensory neurons may be excited directly by inflammatory mediators (e.g., by bradykinin, nitrous oxide, and cytokines) released from white blood cells and Schwann cells around the damaged nerve fibers. Third, injured nerve fibers may be affected by the sympathetic nervous system. Although the latter does not activate primary afferents in normal tissue, injured nerve fibers may become sensitive to adrenergic mediators because neuronal adrenergic receptors are upregulated. A direct connection between afferent and efferent fibers (so-called ephapses) is thought to be the cause. Furthermore, after nerve injury, sympathetic nerve fibers may sprout in the dorsal root ganglion.^{1,3} Currently, the best treatment of peripheral neuropathic pain consists of drugs that reduce the excitability of neurons (e.g., carbamazepine or gabapentin).

THE CENTRAL BASIS OF PAIN

Nociceptive spinal cord neurons

Nociceptors activate synaptically nociceptive dorsal horn neurons (see Fig. 24.1). The latter are either spinothalamic or spinoreticular tract neurons that ascend to supraspinal sites or are local interneurons that are part of the segmental motor or vegetative reflex pathways. A noxious stimulus applied to normal tissue causes a withdrawal reflex that removes the threatened part of the body from the damaging source. Under inflammatory conditions the inflamed tissue is kept in a position that activates nociceptors as little as possible.

Typically, nociceptive spinal cord neurons receive convergent input from numerous sensory neurons in one organ or different organs. Part of the nociceptive dorsal horn neurons are activated by input only from the skin, whereas others are activated by input only from deep tissue (i.e., muscles, tendons, and joints). A large proportion of dorsal horn neurons receive input from both the skin and deep tissue, and others are excited by cutaneous, deep tissue, and visceral stimulation. As a consequence, pain may be poorly localized (especially in deep somatic tissue) and may be even projected. In particular, noxious stimulation of the viscera leads to projection of pain into the skin and deep tissues that are supplied by nociceptors of the same segment.^{1,5}

The spinal cord is under the influence of descending tracts that inhibit or facilitate the spinal nociceptive processing. These descending pathways originate from brain stem nuclei (in particular, the periaqueductal gray matter and nucleus raphe magnus) and descend in the dorsolateral funiculus of the spinal cord.^{12,13}

Generation of the conscious pain response in the thalamocortical system

The conscious pain response is produced in the thalamocortical system (see Fig. 24.1). Different aspects of pain are produced by different networks. Analysis of the noxious stimulus with respect to its location, duration, and intensity (the *sensory-discriminative aspect* of pain) is performed in the *lateral thalamocortical system*, which consists of relay nuclei in the lateral thalamus and primary and secondary somatosensory cortices (SI and SII) in the postcentral gyrus. In these regions, innocuous and noxious stimuli are discriminated.¹⁴ The *affective aspect* of pain (i.e., the noxious stimulus is felt to be unpleasant and causes aversive reactions) is produced in the *medial thalamocortical system*, which consists of relay nuclei in the central and medial thalamus and the anterior cingulate cortex, the insula, and the prefrontal cortex.² These brain structures are part of the limbic system, and the insula may be an interface between the somatosensory and the limbic system. Notably, the limbic regions are involved not only in pain processing. Specifically, the anterior cingulate cortex is activated during different emotions, including sadness and happiness, and parts of the anterior cingulate cortex are also involved in the generation of autonomic responses (they have projections to regions that command autonomic output systems). Other cingulate regions are involved in response selection (they have projections to the spinal cord and the motor cortices) and in orientation of the body toward or away from innocuous and noxious somatosensory stimuli. A role in the process of memory formation/access has also been discussed.¹⁵

Central sensitization

Strong pathologic nociceptive input causes spinal cord hyperexcitability (*central sensitization*) (see Fig. 24.3). Central sensitization amplifies the synaptic processing of nociceptive input in the spinal cord, and thus the thalamocortical system is more strongly activated. Together with peripheral sensitization at the site of inflammation, the spinal hyperexcitability produces *primary hyperalgesia* at the inflamed region. Furthermore, central sensitization generates a zone of *secondary hyperalgesia* in regions adjacent to and remote from the inflamed region, even though the latter areas are in a healthy condition (see Fig. 24.4a). For example, patients with advanced-stage osteoarthritis (OA) often report widespread pain far beyond the OA joint and exhibit lowered pressure pain thresholds in cutaneous and subcutaneous structures of the entire leg.¹⁶ Thus, central sensitization leads to an increase and spread of the pain beyond the site of origin.

Central sensitization can last as long as the nociceptive input persists and disappear when the peripheral input is reduced. However, central sensitization may also outlast the peripheral nociceptive process. In these cases, nociceptive input has probably triggered *long-term potentiation*, a persistent increase in synaptic efficacy.¹⁷ Such a process could account for pain states that persist even when the peripheral nociceptive input has disappeared.

Spinal sensitization is influenced by tracts descending from the brain stem (see flowchart in Fig. 24.3). Experimental evidence suggests that *descending inhibition* of neurons with input from inflamed areas is increased, at least in the acute stage of inflammation, with spinal sensitization being kept under control.¹² However, in severe chronic pain states such as OA or rheumatoid arthritis, some forms of descending inhibition (descending noxious inhibitory control [DNIC]) are almost absent, thus indicating that the endogenous pain control systems became insufficient.^{13,16} Interestingly, this form of descending inhibition is restored after replacement of the OA hip joint.¹⁶ In contrast, *descending facilitation* may support the expansion of receptive fields into healthy areas and thereby promote secondary hyperalgesia¹²; in the case of neuropathic pain, mainly descending facilitation has been observed. Thus, spinal/supraspinal/spinal loops are quite important in the generation of pathologic pain.¹²

Mechanisms of spinal sensitization

Important mechanisms of spinal sensitization are displayed in Figure 24.4b. First, sensitized nociceptors from the inflamed site create stronger input into the spinal cord; that is, they release more transmitters at synapses at the spinal neuron.^{1,7} This is a presynaptic mechanism of spinal sensitization. The main transmitter of sensory afferents is glutamate, and peptidergic C fibers in addition release substance P and CGRP.⁵ Second, enhanced transmitter release from sensitized nociceptors renders the postsynaptic neuron more excitable. This constitutes a postsynaptic mechanism of spinal sensitization. Mechanistically, glutamate activates N-methyl-D-aspartate (NMDA) and non-NMDA receptors (both are ion channels) and metabotropic glutamate receptors in spinal cord neurons.⁵ During noxious stimulation both non-NMDA and NMDA receptors are opened by glutamate, and in particular,

influx of Ca^{2+} through the calcium-permeable NMDA receptors triggers biochemical changes in the neurons that enhance the sensitivity of the neurons. Administration of NMDA receptor antagonists prevents central sensitization and reduces established hyperexcitability. In addition, many spinal nociceptive neurons express receptors for substance P and CGRP, and through activation of these receptors the enhanced release of substance P and CGRP contributes to spinal sensitization.^{1,5} Third, the hyperexcitability of the spinal neuron makes it possible for the neuron to now be activated even by primary afferents that are normally not able to cause suprathreshold excitation of the neuron (dashed lines). Hence the total receptive field of the neuron is enlarged. As a consequence of this sensitization a higher proportion of neurons respond to stimulation of peripheral tissue.^{1,7} Together, these changes produce the areas of secondary hyperalgesia or spreading pain.

Fourth, synaptic processing is further modified by mediators that are produced in the spinal cord and create a change in the milieu there. Numerous spinal neurons (and other cells) produce prostaglandins (mainly PGE_2 and PGD_2).¹⁴ During peripheral inflammation, more PGE_2 is released in the spinal cord and contributes to spinal sensitization. In particular, cyclooxygenase-2-selective inhibitors reduce spinal hyperexcitability by inhibition of spinal prostaglandin synthesis and, as proposed, by enhancing spinal endocannabinoids.¹⁸ By contrast, spinal PGD_2 instead inhibits spinal sensitization during peripheral inflammation.⁷ Glial cells in the spinal cord can significantly contribute to the generation of pain states, particularly

neuropathic pain¹⁹ but also experimental models of OA.¹⁵ On stimulation, neuroglia secrete a number of mediators such as nitrous oxide, neurotrophins, and proinflammatory cytokines, and neutralization of such mediators may attenuate hyperalgesia.¹⁹

Importantly, inhibitory transmitters such as γ -aminobutyric acid (GABA) and opioids are able to reduce spinal sensitization by decreasing release of transmitters and depolarization of postsynaptic neurons. An important mechanism of spinal sensitization may be the loss of segmental inhibition that is normally provided by GABAergic interneurons.⁵

CONCLUSION

Pain is an important component of suffering from disease, and therefore treatment of pain is an absolute necessity in clinical medicine. In a wider sense, pain is also an important element of the so-called illness response. The symptoms of diseases result not only from local disease processes but also from mechanisms in the central neurons system that respond to challenges such as inflammation, infection, and injury in a coordinated fashion. In fact, plenty of evidence has shown autonomic/endocrine/immune interactions to be related to acute and chronic pain.²⁰ In this respect, pain therapy may not only just attack a clinical symptom but also modify the further course of disease.

Effects of the neuroendocrine system on development and function of the immune system

■ MAURIZIO CUTOLO ■ RAINER H. STRAUB

- The function of the hypothalamic-pituitary-adrenal (HPA) axis is not completely normal in patients with chronic inflammatory diseases.
- Levels of HPA axis hormones are inadequately low in relation to levels of circulating proinflammatory cytokines.
- Serum concentrations of adrenal androgens are mostly decreased.
- The influence of estrogens on immunity is rather complex depending on many different factors; estrogens can be proinflammatory and antiinflammatory but enhance B-cell immunity (autoimmunity).
- The steroid hormone vitamin D modulates many aspects of innate and adaptive immunity.
- The cortisol nadir at midnight and the parallel increase in immunostimulatory hormones such as melatonin and growth hormone drive the nightly increase in tumor necrosis factor and interleukin-6 concentrations and thus morning clinical symptoms in rheumatoid arthritis.
- Many alterations of neuroendocrine pathways and chronic inflammatory disease sequelae can be explained by an evolutionarily selected program that redirects energy-rich fuels from stores (liver, muscle, fat tissue) to the activated immune system during the night.

INTRODUCTION

Independent observations already being made in the 19th century by Trousseau, Charcot, and Bannatyne indicated that pregnancy is favorable in rheumatoid arthritis (RA), as summarized in the Nobel Prize lecture of the rheumatologist Philip S. Hench on December 11, 1950.¹ Dr. Hench wrote as follows²:

after 1931, records of these cases [of pregnancy with RA] were more carefully made and assembled ... because of my growing belief that this phenomenon of relief [from arthritic disability] was analogous to, if not identical with, that which may occur during jaundice, and that the same agent might be responsible for the relief both during pregnancy and jaundice.

These observations linked for the first time immune/inflammatory diseases to hormones, and this was firmly established by the enormous treatment success achieved through administration of endogenous glucocorticoids during the 1950s.³ In addition, the obvious female preponderance in the prevalence and incidence of autoimmune diseases spoke for the role of sex hormones (e.g., estrogens).⁴ This female predominance is particularly evident in the reproductive years, when sex hormone levels are highest in women (estrogens) and men (androgens).

Furthermore, the induction of ovulation by gonadotropin, a gonadotropin-releasing hormone analogue, or clomiphene can result in flares, embryonic losses, or fetal deaths in patients with systemic lupus erythematosus (SLE) or antiphospholipid syndrome.⁵ Again, this indicates that generally an increase of female sex hormones can worsen autoimmune diseases. In sharp contrast seems to be the finding that some women develop an autoimmune disease such as RA after menopause when serum sex hormone levels fall dramatically. This is not an unresolvable paradox considering the

mentioned role of sex hormones, as will be demonstrated later, because sex hormones have very different effects on different types of immune cells; in addition, their peripheral metabolism plays an important role.⁴ This is particularly true in menopause with the increased physiologic activity of the aromatase complex in peripheral tissues (e.g., adipose tissue). Increased activity of this enzyme complex leads to higher peripheral synthesis of estrogens from androgens, which has a stimulating effect on B-cell immunity.⁶

The clear connection between stressful life events on the one hand and exacerbations of autoimmune diseases on the other demonstrates a role for steroidal hormones or neurotransmitters in these diseases (e.g., cortisol and noradrenalin).^{7,8} Similarly, the phenomenon that in different diseases hemiplegia spares the paretic side from inflammatory signs and symptoms supports an important propagating role for the nervous system.⁹ Moreover, the circadian undulation of symptoms in autoimmune diseases links the rhythms of the central nervous and neuroendocrine systems to immunologically mediated phenomena. In recent years, we have started to recognize that the neuroendocrine system is important in providing energy-rich fuels to the activated immune system,¹⁰ the long-standing supply of which in chronic inflammatory diseases leads to many unwanted disease sequelae.¹¹ These clinical findings have opened up totally new avenues for understanding the impact of the neuroendocrine system on the development and function of the immune system in chronic inflammatory diseases.

NEUROENDOCRINE SYSTEM

Fig. 25.1 is a representation of the different endocrine and neuronal axes relevant to the neuroendocrine system. The hypothalamic-pituitary-adrenal (HPA) axis influences many immunologic mechanisms (see later). Progesterone, dehydroepiandrosterone (DHEA), and androstenedione are precursor hormones of the HPA axis that can be converted to downstream sex hormones. Sex steroid action can take place in the same cells where conversion occurs (intracrinology).¹² In postmenopausal women, nearly 100% of sex steroids are synthesized in peripheral tissues from precursors of adrenal origin, as mentioned earlier (in older men peripheral conversion depends on age and can be up to 80%). After menopause and during aging, the HPA axis can take over various functions of the hypothalamic-pituitary-gonadal (HPG) axis (Fig. 25.2), and this can and have an effect on immune/inflammatory reactivity. Peripheral conversion can be influenced by local cytokines, hormones, and neurotransmitters.¹³ The well-known undulation of symptoms of autoimmune diseases during the menstrual cycle demonstrates the influence the HPG axis. In this situation, gonadally produced estrogens and androgens can bypass the conversion steps via progesterone and DHEA (see Fig. 25.2, yellow box). Beyond steroid hormones, vitamin D (or, better, D hormone as active metabolite), prolactin, melatonin, growth hormone, insulin-like growth factor 1, and other hormones demonstrate immune-modulating properties.¹⁴⁻¹⁶

The central neuroendocrine system is activated upon peripheral inflammation that stimulates the HPA axis. In recent years, this stimulation has been recognized as part of the energy appeal reaction and water retention reaction,^{10,11} while the HPG axis and the somatotrophic axis are switched off. The major immune stimuli for the HPA axis and the sympathetic nervous system are circulating interleukin-6 (IL-6), interferon- γ (IFN- γ), and tumor necrosis factor (TNF) and local cytokines such as IL-6, TNF, IL-17, and IL-1 β , which directly activate sensory afferents.¹⁷ It is important to mention that acute stimulation of neuroendocrine centers can lead to markedly

Fig. 25.1 Neuroendocrine pathways relevant in rheumatic diseases. Neuroendocrine pathways link the central nervous system with the periphery by way of hormones and nerve fibers (neurotransmitters). Some important cells are shown to indicate some targets in inflamed tissue and lymphoid organs. Autonomic efferents comprise sympathetic and parasympathetic nerves with the main sympathetic neurotransmitters noradrenaline (plus neuropeptide Y, adenosine triphosphate, and endogenous opioids) and with the main parasympathetic neurotransmitter acetylcholine. The sensory nervous system bears vesicles with substance P and calcitonin gene-related peptide. ACTH, adrenocorticotropic hormone; ASD, androstenedione; CRH, corticotropin-releasing hormone; DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; NK, natural killer; POMC, pro-opiomelanocortin-derived proteins (other than ACTH); RAAS, renin-angiotensin-aldosterone system; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (or thyrotropin).

different behavior of these axes compared with chronic stimulation due to the relative insufficiency of stress axes (exhaustion).

Hypothalamic-pituitary-adrenal axis Influence of hypothalamic-pituitary-adrenal axis hormones on the development of the immune system (animal models)

There are tight connections between the HPA and somatotrophic axes and the thymus.¹⁸ For example, glucocorticoids have long been known to inhibit thymocytes, and thymocytes possess all enzymes to generate glucocorticoids in the thymic microenvironment.¹⁹ Adrenocorticotropic hormone (ACTH) inhibits mitogenesis of immature and mature thymocytes,²⁰ DHEA suppresses proliferation of thymocytes,²¹ and DHEA induces thymocyte apoptosis by upregulation of Fas and FasL.²² Inversely, thymic factors such as thymulin or cytokines influence the hypothalamic-pituitary axis (e.g., growth hormone secretion), which led to the concept of a reciprocal feedback loop between the hypothalamic-pituitary axis and the thymus.¹⁸

In addition, growth hormone and prolactin were shown to be important connectors of the pituitary gland and the thymus.¹⁸ These interconnections between the hypothalamic-pituitary axis and the thymus most probably play an important role in the aging process, in which the integration of this network is disrupted and the thymus undergoes involution.²³ Because the thymus is the primary T-lymphopoietic organ during ontogenesis, its

age-related involution with morphologic alterations is, in part, responsible for the decline in antigen-specific T-lymphocyte immune functions. It is still unclear whether the neuroendocrine connection between the hypothalamic-pituitary axis and the thymus is altered in human chronic inflammatory autoimmune disease.

Progesterone inhibits differentiation of bone marrow-derived dendritic cells, and it also influences maturation of dendritic cells.^{24,25} In addition, progesterone might influence B-lymphocyte development because progesterone receptors have been demonstrated in premature B cells.²⁶ The inhibiting role of glucocorticoids on B-lymphocyte development has been demonstrated in the mouse.²⁷ Although most of these findings play relevant roles in the immunophysiology of rodents, their impact has never been demonstrated in humans with or without a chronic autoimmune disease.

Influence of hypothalamic-pituitary-adrenal axis hormones on the immune system

Although corticotropin-releasing hormone (CRH), as a major hormone of the hypothalamus, has a strong antiinflammatory role in the general regulation of the HPA axis, CRH produced locally exerts many proinflammatory effects.²⁸ The use of a CRH receptor type 1 antagonist has been found to ameliorate adjuvant arthritis.²⁹ Similarly, local administration of the pituitary hormone ACTH exerts some stimulatory activities on cytotoxic T lymphocytes,²⁰ and T lymphocytes, B lymphocytes, and macrophages possess melanocortin receptors.³⁰ ACTH can bind to all melanocortin

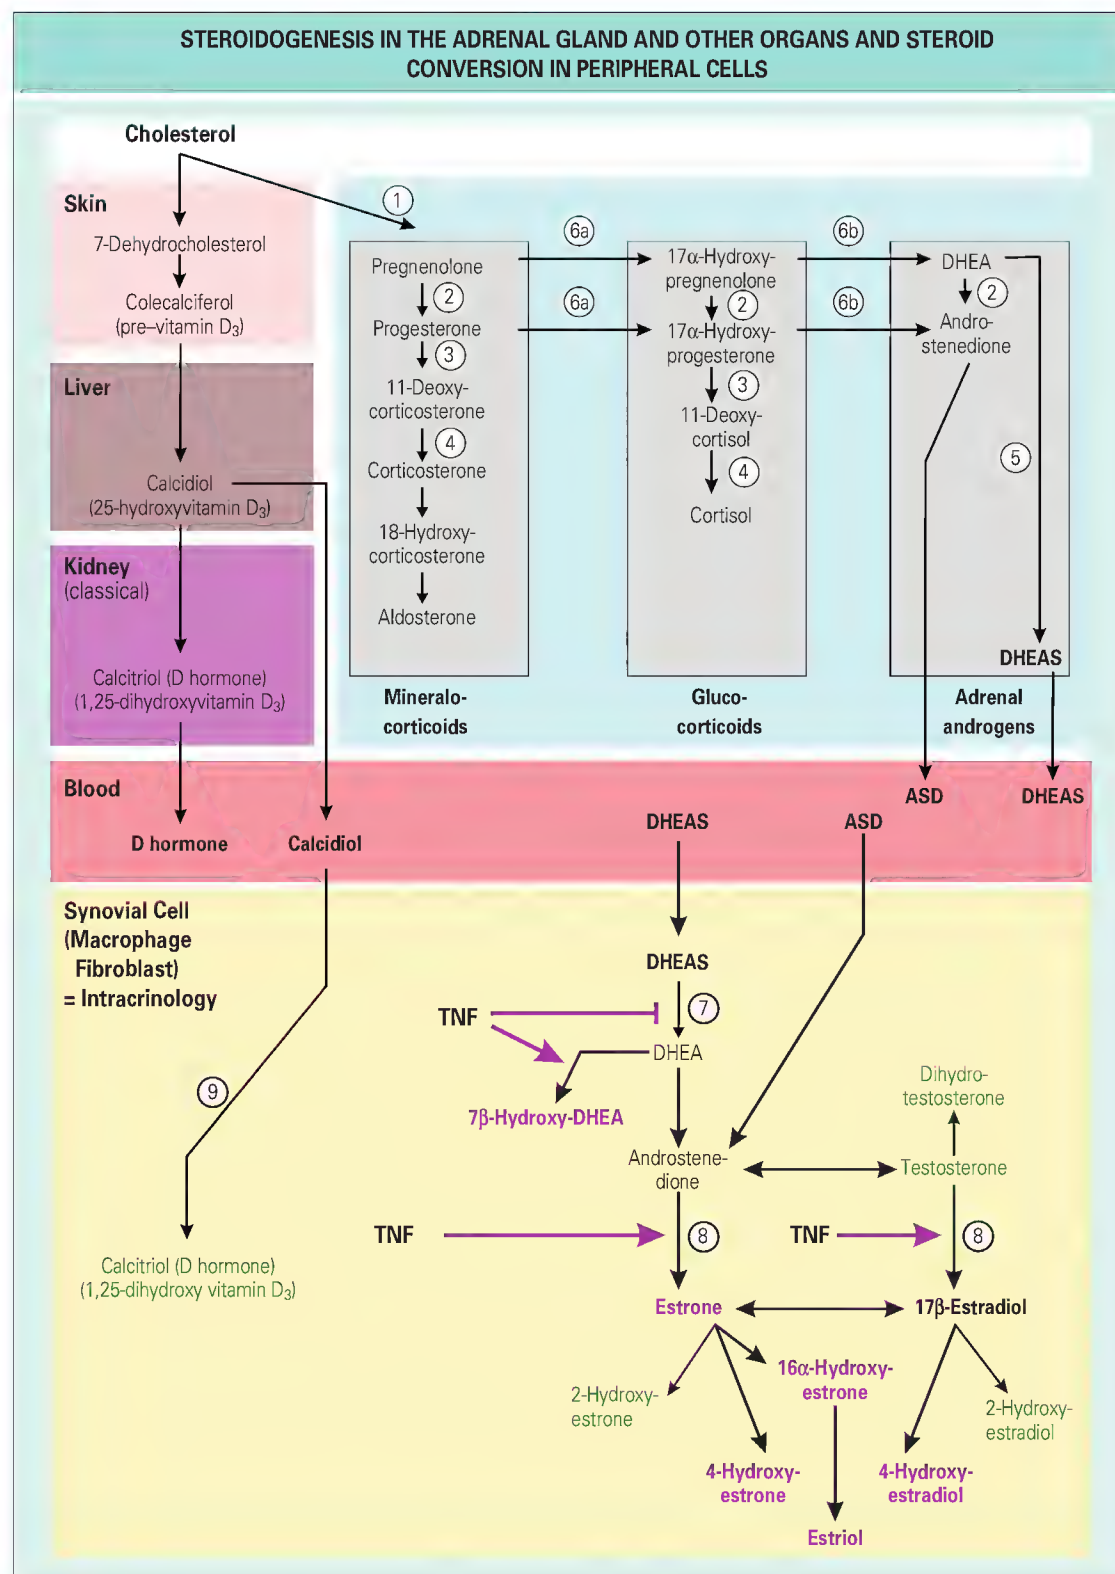

Fig. 25.2 Steroidogenesis at the level of different organs and steroid conversion at the level of peripheral cells. The size of the font indicates availability, production, and concentration of the respective factors (small font = little; big font = much). The large grey box on the upper right shows steroidogenesis in the adrenal gland under healthy conditions. The small brown and violet boxes on the upper left show vitamin D pathways in different organs. The bottom section (yellow box) depicts the conversion of steroid hormones in peripheral cells such as the macrophage or fibroblast (intracrinology). The violet and green colors in the yellow box indicate a proinflammatory and an antiinflammatory influence, respectively. DHEAS is converted to downstream androgens and estrogens. The proinflammatory tumor necrosis factor (TNF) interferes with several hormonal conversion steps (a line with a bar at the end indicates inhibition, whereas an arrow indicates stimulation). Circled numbers: 1, P450 side-chain cleavage enzyme; 2, 3β-hydroxysteroid dehydrogenase; 3, P450c21 (21-hydroxylase); 4, P450c11 (11α-hydroxylase); 5, DHEA sulfotransferase; 6a and 6b, P450c17, an enzyme with two activities (17α-hydroxylase and 17/20-lyase); 7, DHEAS sulfatase; 8, aromatase complex; 9, α1-hydroxylase (occurs in cells equipped with this enzyme, i.e., macrophages). ASD, androstenedione; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate.

receptors type 1 to 5, and signaling via type 4 and 5 receptors leads to proinflammatory events via phosphoinositol hydrolysis, protein kinase C activation, and stimulation of the JAK/STAT pathway.³¹

In contrast, glucocorticoids possess antiinflammatory effects *in vitro* on almost all immune cells and inflammatory bystander cells studied. This is particularly true if concentrations of cortisol or corticosterone are equal to or above 10^{-7} mol cortisol per liter and if, *in vivo*, this elevation lasts for a longer period of time (days to weeks). In contrast, if, *in vivo*, glucocorticoids rise for only a short period of time (hours), they might exert overall immunostimulatory effects by inducing redistribution and migration of immune cells.^{32,33}

Glucocorticoids and progesterone shift the T-cell immune response to a helper T cell type 2 (Th2) immune reaction.³⁴ This phenomenon is most probably an important factor during pregnancy to save the semiallogeneic embryo from the maternal immune system.³⁵ In addition, this cytokine shift is also an important factor for pregnancy-related amelioration of diseases such as RA and multiple sclerosis, but it can be a stimulating factor in SLE in the second trimester.

Finally, adrenal androgens were found to have several antiinflammatory effects by inhibiting cytokines such as IL-2, IL-6, TNF, interferon- γ , and others.³⁶ These antiinflammatory effects are attributed to the biologically active DHEA but not its biologically inactive precursor DHEA sulfate (DHEAS). In the circulation, DHEAS is the pool for DHEA, which is converted from DHEAS in peripheral cells.

It was thought that biologically active DHEA has effects opposite to those of cortisol. This DHEA effect prompted several therapeutic studies in patients with SLE (characterized by low serum DHEA levels), which

demonstrated a mild beneficial effect in this disease.^{37,38} A similar positive role of DHEA was not demonstrated in RA, which most probably depends on conversion of DHEA to proinflammatory 7 β -hydroxy-DHEA and other proinflammatory pathways³⁹ (see Fig. 25.2, yellow box). The importance of all these hormones in influencing T regulatory cells or T effector cells is still a matter for further study.

Hypothalamic-pituitary-adrenal axis hormones and the pathophysiology of chronic inflammatory diseases

The lack of HPA axis hormones worsens inflammatory diseases, both in animal models and in patients.^{40,41} Every acute inflammatory event—for example, simulated by injection of IL-6⁴²—increases circulating levels of HPA axis hormones, but in patients with chronic inflammatory diseases, hormone levels are not increased although IL-6 levels are continuously elevated⁴³ (Fig. 25.3a). Importantly, the function of the HPA axis is not completely normal in patients with chronic inflammatory diseases, and levels of HPA axis hormones are inadequately low in relation to circulating and stimulating cytokines.^{44,45} Habituation phenomena accompanied by cytokine-induced blockade of hormone synthesis lead to their inadequate levels in chronic inflammatory diseases.⁴⁶ In addition, concentrations of adrenal androgens are mostly decreased due to reorganization of adrenal steroidogenesis, which leads to a preponderance of cortisol relative to other adrenal hormones. This is most probably due to inhibition of adrenal 17,20-lyase activity of P450c17 (see enzyme 6b in Fig. 25.2). Importantly, the preponderance of cortisol relative to adrenal androgens is a feature of nearly all chronic inflammatory diseases.¹⁰ This preponderance was recently explained by a new theory as a reallocation program of energy-rich fuels

Fig. 25.3 Inadequately low levels of cortisol in relation to cytokine levels and influence of 17 β -estradiol on target immune cells. (a) Inadequate secretion of cortisol in relation to inflammation. The right panel shows that subcutaneous (SC) injection of interleukin-6 (IL-6) leads to a large increase in serum cortisol in healthy subjects (HS).⁴² The left panel shows that injection of IL-6 leads to very similar serum levels of IL-6 in healthy individuals compared with patients with rheumatoid arthritis (RA).⁴³ However, serum cortisol levels are not increased in patients with RA compared with healthy individuals as demonstrated in the right panel.⁴³ (b) Influence of estrogens on important proinflammatory and antiinflammatory pathways in different cell types. The concentration of 17 β -estradiol is given on the y-axis. Depending on the concentration of 17 β -estradiol (E2), factors in orange boxes are stimulated and factors in blue boxes are inhibited by estrogens. DC, dendritic cell; IFN- γ , interferon- γ ; TGF- β , transforming growth factor- β ; TNF, tumor necrosis factor.

(amino acids) from muscle to the activated immune system, which is supported by a loss of androgens.¹⁰

Not only is HPA axis organ function altered, but conversion and degradation of secreted hormones in peripheral tissue are altered. In cells of inflamed tissue, activation of the biologically inactive DHEAS to the biologically active DHEA is inhibited by TNF⁴⁷ (see Fig. 25.2, yellow box), and TNF activates the aromatase complex, which leads to the formation from androgens of proinflammatory estrogens, such as 16-hydroxylated estrogens (see Fig. 25.2, yellow box).⁴⁸ All these peripheral phenomena lead to a more proinflammatory environment in inflamed tissue and might explain otherwise unexpected immune/inflammatory reactions and therapeutic results, even in the presence of normal serum hormonal concentrations.

Hypothalamic-pituitary-gonadal axis

Influence of hypothalamic-pituitary-gonadal axis hormones on the development of the immune system (animal models)

In animal studies, 17 β -estradiol at high concentrations leads to a suppression of B-lymphocyte lineage precursors. In addition, IL-7-responsive B-lineage precursors are greatly expanded in genetically hypogonadal female mice. Estrogen replacement in these mice resulted in a dose-dependent reduction in B-cell precursors.⁴ At pregnancy levels, 17 β -estradiol induced a downregulation of B-lymphopoietic cells in bone marrow of young ovariectomized mice mediated through both estrogen receptors.⁴

In addition to their effects on B cells, estrogens have a strong influence on the development and maintenance of T cells. In estrogen receptor-intact animals, 17 β -estradiol (pregnancy levels) induced profound thymus involution.⁴ Treatment with 17 β -estradiol (pregnancy levels) for 4 weeks decreased thymus cellularity and the percentage of CD4+ cells in the spleen, which was not observed in double estrogen receptor-deficient mice.⁴ Thus 17 β -estradiol inhibits B-cell and T-cell precursor development. Whether the 17 β -estradiol-induced changes are positive or negative in human chronic inflammation remains to be established because autoaggressive but also autotolerant regulatory B and T cells might be eliminated.

Finally, 17 β -estradiol has been shown to promote the differentiation of dendritic cells from bone marrow precursors *in vitro*, and this effect is mediated via estrogen receptor- α .⁴⁹ Raloxifene and tamoxifen, two estrogen antagonists, inhibited the differentiation of estrogen-dependent dendritic cells from bone marrow precursors *ex vivo* in competition experiments with physiologic levels of 17 β -estradiol.⁵⁰

In conclusion, these experiments in animals and with cells of rodents demonstrate that 17 β -estradiol has inhibitory effects on the development of B cells and T cells. Similar inhibitory effects were demonstrated for testosterone with regard to the thymus.²¹ It is currently unclear how these sex hormones influence development of immune cell precursors in patients with autoimmune diseases. This can be an important line of research, because sex hormones might bias the immune response toward an aggressive autoimmune response already many years before outbreak of the disease.⁵¹

Influence of androgens and estrogens on the function of the immune system (studies in humans)

In general, in physiologic concentrations androgens suppress the immune responses.⁵² Fig. 25.3b summarizes the most important effects of high and low concentrations of estrogens on different types of cells involved in chronic inflammation.⁴ At pregnancy levels (increase), 17 β -estradiol inhibits important proinflammatory pathways such as TNF, IL-1 β , IL-6, MCP-1, inducible nitric oxide synthase expression, production of matrix metalloproteinases (MMPs), and activity of natural killer cells, whereas 17 β -estradiol at the same concentration stimulates antiinflammatory pathways such as IL-4, IL-10, transforming growth factor- β (TGF- β), tissue inhibitors of MMP (TIMPs), and osteoprotegerin (see Fig. 25.3b). At lower concentrations, 17 β -estradiol stimulates TNF, IFN- γ , IL-1 β , and the activity of natural killer cells. This dichotomy of 17 β -estradiol at high versus low concentrations is not observed for B cells, because antibody production is still stimulated throughout the full concentration range (see Fig. 25.3b). Consequences of these 17 β -estradiol effects for chronic inflammation are summarized in the next section.

Hypothalamic-pituitary-gonadal axis hormones and the pathophysiology of chronic inflammatory diseases

B cells, T cells, and antigen-presenting cells (macrophages/dendritic cells and B cells) are decisive for the initiation of autoimmune diseases. One might separate two clinically important phases of an autoimmune disease: (1) an asymptomatic phase, and (2) a symptomatic phase (after disease outbreak). Disease outbreak means involvement of a target organ and target

tissue leading to the classical clinical signs of visible and functionally relevant inflammation. Recent important work in the field of RA has shown that autoimmune phenomena are already present and initiated more than 10 years before disease outbreak.^{53,54}

In the asymptomatic phase, T cells, B cells, and antigen-presenting cells play an important hidden role because clonal expansion of autoreactive T cells and B cells happens without overt disease symptoms. Because the influence of estrogens on these players is different from that on other cell types, estrogens can have quite opposite roles depending on the involved cells. If B cells play a central role by antigen presentation, autoantibody production, and/or bystander cytokine production, they will speed up the outbreak of the disease in the early reproductive years. Because men never experience these high estrogen or progesterone levels and counteract these hormones by testosterone, the apparent gender dimorphism of autoimmune diseases during the reproductive period of women can be explained. However, the differences between men and women do not exist in peripheral inflammatory tissues (e.g., synovial tissue in RA) because estrogens are produced locally by an activated aromatase complex in both sexes (see earlier).

If tissue-destructive T cells and B cells play an equally important role in initiation of a chronic inflammatory disease, it is hypothesized that the onset of disease in a woman will be delayed because 17 β -estradiol may inhibit T-cell autoimmunity but always stimulates B-cell autoimmunity. In such a situation, the onset of the disease might be shifted to the late reproductive phase or postmenopausal period. If tissue-destructive T cells play the most important role (no role for B cells), the onset of the disease should be expected in the postmenopausal phase when serum concentrations of 17 β -estradiol but also progesterone decline.⁴ Thus ovariectomy in animal models or menopause in women is stimulatory for autoimmune arthritis and other autoimmune diseases of late onset and T-cell dominance.

The location of tissue inflammation in an autoimmune disease is defined by a tissue autochthonous autoantigen (or several autoantigens). Once a disease has entered the highly inflammatory symptomatic phase, many other cell types become involved depending on the major location of the autoimmune disease (in the brain, in the joint, in the kidney, in the liver, etc.). For example, in the joint, macrophages, fibroblasts, osteoclasts, osteoblasts, adipocytes, endothelial cells, and many more gradually become involved in the inflammatory process. Depending on the predominant cell types involved, 17 β -estradiol and also progesterone might have quite different effects on these bystander inflammatory activities of participating cells.⁴

All players (including B cells, T cells, and antigen-presenting cells) might have very different capacities to take up and to metabolize estrogens.⁴⁸ Metabolism of estrogens depends on transport into cells, desulfation of sulfated estrogens, sulfatation of nonsulfated estrogens, androgen aromatization, and estrogen conversion to downstream hydroxylated or methylated estrogens (see Fig. 25.2, yellow box). In addition, upregulation or downregulation of estrogen receptors α and β (in cells or on the cell surface), of coactivators, and of corepressors might well depend on involved cells and microenvironmental conditions such as accompanying hypoxia and the surrounding cytokine cocktail. In addition, it has been nicely demonstrated, but in one animal model, that 17 β -estradiol accelerates immune complex glomerulonephritis but may ameliorate focal sialadenitis, renal vasculitis, and periarticular inflammation.⁵⁵ This might suggest that quite different pathologic conditions might even be present in the same human individual so that estrogens (or their peripheral metabolites) may have beneficial effects on one aspect of the disease but a different influence on other mechanisms. This depends most probably on involved cell types, on concentrations, and notably on peripheral estrogen metabolism rate.^{4,13}

Studies in the last decade also demonstrated that the small change in estrogen or progesterone levels during therapy with oral contraceptives or hormone replacement therapy has variable power to increase the risk or severity of a B cell-related autoimmune disease (with more clear effects on overt disease).⁴ One understands that at postmenopausal levels estrogens can even stimulate several immune mechanisms due to their bimodal role (see Fig. 25.3b).

In addition, there are important similarities between chronic inflammatory diseases and inflammatory reactions in certain types of cancer, such as breast cancer and prostate cancer. In inflammatory tissue of patients with RA, steroid hormone precursors are converted mainly into 16-hydroxylated estrogens, which are proliferative and covalently bound to estrogen receptor- α .⁵⁶ In contrast, generation of antiproliferative 2-hydroxylated estrogens is blocked. Conversion can happen in synovial macrophages and fibroblasts (see Fig. 25.2). Similarly, macrophages in breast cancer tissue can convert precursor hormones to 16-hydroxylated estrogens with a similar increase of estrogenic effects.⁵⁷ Like 17 β -estradiol, the converted

16-hydroxylated estrogens can stimulate important growth factors such as TGF- β , basic fibroblast growth factor, keratinocyte growth factor, and bone morphogenetic proteins.⁴ This is in agreement with the important growth-supporting role of 17 β -estradiol during pregnancy. In both chronic inflammatory disease and cancer, in which overshooting growth responses play a decisive pathogenic role, the 17 β -estradiol-stimulated increase in these growth factors is most probably harmful.

VITAMIN D IN CHRONIC INFLAMMATORY AUTOIMMUNE DISEASES

Vitamin D is a steroid hormone because it is generated from the steroid backbone of cholesterol, which is converted to the active D hormone (see Fig. 25.2). Epidemiologic evidence clearly indicates a significant association between low levels of serum vitamin D (25-hydroxyvitamin D₃ [25(OH)D₃]) and increased incidence of autoimmune diseases (role as a risk factor), including RA, SLE, type 1 diabetes mellitus, and multiple sclerosis.⁵⁸ In addition, it has also been demonstrated that lower levels of vitamin D are associated with higher disease activity in RA. Likewise, vitamin D supplementation is associated with a reduced risk of RA, type 1 diabetes mellitus, and multiple sclerosis.⁵⁸

The presence of vitamin D receptors in cells of the immune system and the fact that several of these cells produce the active vitamin metabolite (1,25-dihydroxyvitamin D₃ [1,25(OH)₂D₃]) (intracrinology) justify the view that vitamin D could have immunoregulatory effects on dendritic cells, Th1 and Th17 cells, as well as B cells.⁵⁸ With respect to B lymphocytes, it was shown that 1,25(OH)₂D₃ does exert direct effects on B-lymphocyte homeostasis.⁵⁹ In addition to confirming direct vitamin D receptor-mediated effects on B-lymphocyte proliferation and immunoglobulin production, this study also highlighted the ability of 1,25(OH)₂D₃ to inhibit the differentiation of B lymphocytes into plasma cells and class-switched memory B cells, which suggests a potential role for vitamin D in B-lymphocyte-related disorders such as SLE (characterized by severe deficiency).⁵⁹

Vitamin D, like cortisol and sex hormones, regulates both innate and adaptive immunity, mainly potentiating the innate immune response and suppressing the adaptive immunity.⁶⁰ Potentiation of the innate immune response at surfaces exposed to the environment establishes an excellent first-line defense against pathogens. Thus vitamin D would be expected to enhance resistance to acute infections in the skin, lungs, gastrointestinal tract, bladder, and other epithelial surfaces. In fact, vitamin D is synthesized at an increased rate inside monocytes/macrophages in the presence of bacterial and viral infections, and stimulates the synthesis of antimicrobial peptides such as cathelicidins, which contribute to bacterial killing and initial defense against pathogens like *Mycobacterium tuberculosis*.⁶¹ Those mechanisms might underlie the beneficial effects exerted by graded sun exposure, which was used to treat chronic tuberculosis in sanatoriums at the beginning of the 20th century. Interestingly, a systematic review of data for the period between 1971 and 2006 for 11 countries and regions around the world confirmed a seasonal pattern of tuberculosis, with the most prominent peak during winter and spring.⁶¹ If infections represent a risk factor for development of RA, seasonality of infections and vitamin D serum levels might play an important role.

Furthermore, at normal serum concentrations, vitamin D downregulates Th1-dependent immune responses, and its intake or increased synthesis during UV light exposure has been found to be inversely associated with the risk of RA. Interestingly, significantly lower serum levels of 1,25(OH)₂D₃ were observed in patients with RA from the north of Europe (less UV exposure higher incidence of RA) than in those from the south, linked to a different duration of sunshine.⁶² These effects of vitamin D indicate an important role for this hormone in autoimmune diseases.

CIRCADIAN RHYTHMS AND THE IMMUNE SYSTEM

The term *circadian rhythm* refers to the 24-hour cycles in the physiologic processes of living organisms. In RA it is observed that symptoms are worse in the very early morning hours, and a similar pattern has been described for asthma, gout flares, angina pectoris, and others. It is remarkable that the improvement of morning stiffness in RA induced by prednisolone after 6 months is similar in magnitude to the improvement of morning stiffness during a single day (from morning to evening). Over both time periods—the term of a clinical trial and the course of 1 day—an improvement of 40% to 50% can occur. Imagine, therefore, a situation in which an investigator in a clinical trial did not pay attention to the specific time of examination and

recorded improvement that reflected the diurnal variation as much as a sustained treatment effect. Circadian rhythms are a basis for variations in the immune/inflammatory response.

Both IL-6 (Fig. 25.4a) and TNF display a circadian rhythm, with maximum levels in the very early morning hours.⁶³ In healthy subjects, the peak value of IL-6 is found at about 6 AM. In patients with RA, the peak value of IL-6 appears at 7 AM. In healthy subjects, IL-6 serum levels are approximately 2 to 4 pg/mL, whereas in RA patients these levels are 20 to 40 pg/mL. Thus the amplitude of the curve of cytokine production is higher and the curve is broadened in RA compared with control subjects.⁶⁴ In healthy subjects, serum levels of IL-6 usually decrease by 9 AM, whereas in RA patients, these levels can remain elevated until 11 AM. The increased amplitude and the broadened curve in the morning hours are important for the morning symptoms. In view of these observations the key question is what is driving the circadian oscillation of serum levels of cytokines.

The cycle of the HPA axis has a maximum in the early morning hours at 8 AM and a nadir at midnight (see Fig. 25.4a). Detailed analyses of the circadian curves of cytokines and cortisol have revealed a lag time between the cortisol rise compared with the increase in cytokine of approximately 60 to 120 min.⁶⁵ From this study and a recent analysis of the results of several independent investigations,⁶³ it appears that morning cytokine levels can drive the increase in cortisol. The cortisol rhythm in healthy subjects does not differ from that in patients with RA when disease activity is relatively low to moderate. This similarity holds for the period, the amplitude, and the time of the minimum and peak of the cycle (see Fig. 25.4a).

Although levels of cytokine 10 times higher than normal should drive a stronger cortisol response (see Fig. 25.4a), it is notable that the serum levels of cortisol are similar in healthy control subjects and patients with RA. This phenomenon was discussed earlier and was called *inadequate secretion of cortisol in relation to inflammation* (relative insufficiency). The reasons for this inadequacy relate in part to inhibition (or exhaustion) of the HPA axis by chronically elevated levels of cytokines. In other words, secreted cortisol is unable to dampen the proinflammatory response. For this reason, cytokine levels stay high.

At present, it is thought that the cortisol nadir at midnight and the parallel increase of the immunostimulatory hormones melatonin, prolactin, and growth hormone drive the increase of nightly TNF and IL-6.⁶⁴ Subsequently, these two cytokines drive cortisol, and the later cortisol increase finally dampens the cytokine surge, and so on. Because the circadian rhythm is generated in higher brain centers of the endocrine and nervous systems (in the hypothalamus), the circadian rhythms of cytokines mirrors the activity of neuroendocrine centers in the brain. This provides a strong indication that neuroendocrine pathways influence disease-related pathophysiology and might suggest new options for therapeutic interventions.

A recent theory explained nighttime activation of the immune system as an evolutionarily selected circadian program that allocates energy-rich fuels to brain and muscle during the day (daytime consumers) and to the immune system and growth-related pathways during the night (nighttime consumers) (see Fig. 25.4b).¹⁰ This circadian program is tightly coupled to the function and action of the neuroendocrine system (see Fig. 25.4b).

The theory further explains that continuous use of energy reallocation programs to support the activated immune system leads to disease sequelae such as sickness behavior, anorexia, malnutrition, muscle wasting and cachexia, cachectic obesity, insulin resistance with hyperinsulinemia, dyslipidemia, increase of adipose tissue near inflamed tissue, alterations of steroid hormone axes, elevated sympathetic tone and local sympathetic nerve fiber loss, decreased parasympathetic tone, hypertension and volume overload, inflammation-related anemia, and osteopenia.^{10,11}

Translational studies: circadian or circannual therapies

One would think that a therapeutic increase in circulating glucocorticoids should alleviate symptoms in patients with RA. Glucocorticoids are usually given after the patient awakes in the morning at a time when gelling and stiffness are already at a maximum, but this is not the optimal moment during the day. Recent data from a double-blind, placebo-controlled, randomized study involving hundreds of patients with RA demonstrated a more marked and significant effect on morning stiffness and serum IL-6 level when glucocorticoids are given at 2 AM in the night.⁶⁶ The question is why immunosuppressive treatment with glucocorticoids can inhibit proinflammatory sequelae better when given at 2 AM.

These observations are very important in understanding antiinflammatory counterregulation of immune responses. It has been demonstrated that glucocorticoids induce the transcription of the inhibitor of κ B (I κ B α) gene, which results in an increased rate of I κ B α protein synthesis and inhibition

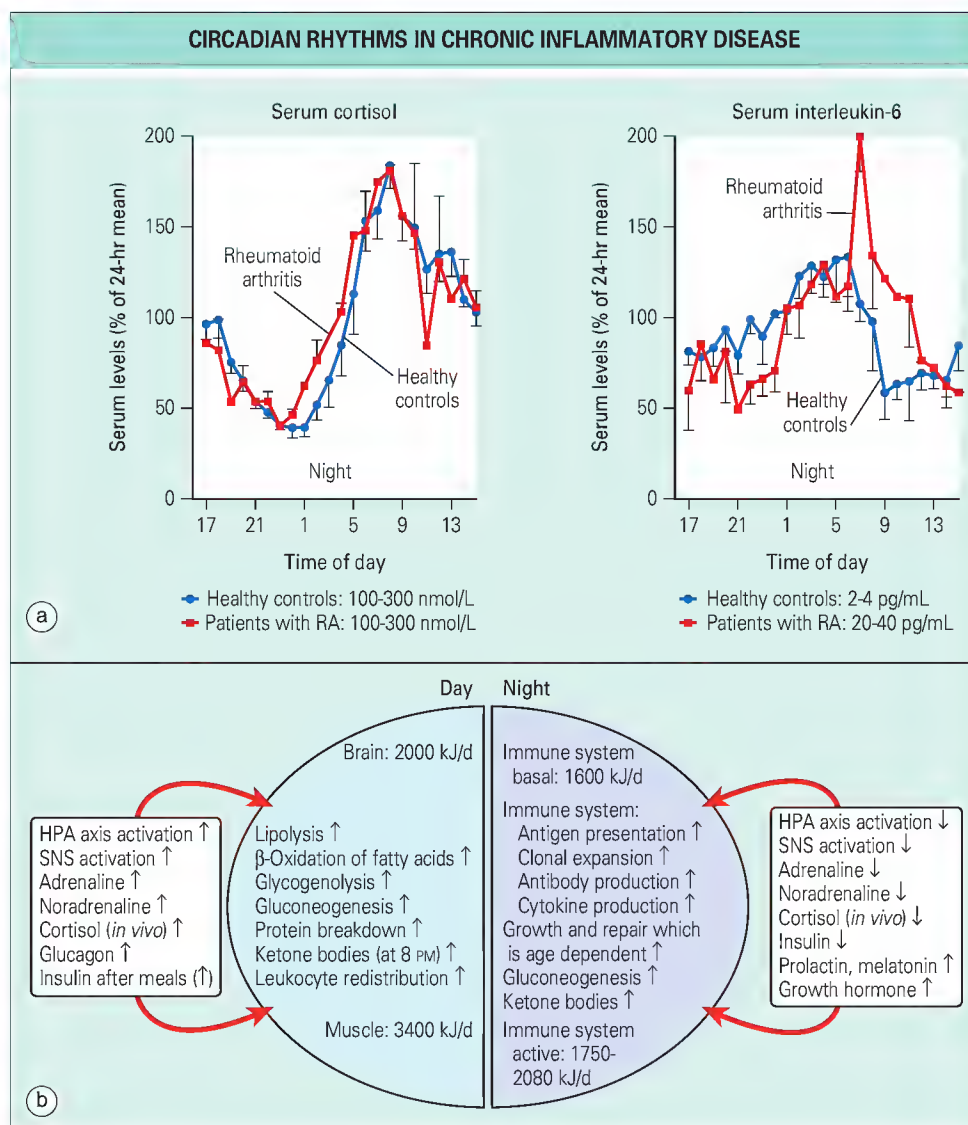

Fig. 25.4 (a) Circadian rhythm of cortisol and interleukin-6 (IL-6) in healthy subjects and patients with rheumatoid arthritis (RA). The data are given in percent of the 24-hour mean. Despite the markedly increased serum levels of IL-6 in RA compared with healthy subjects, the circadian rhythm of cortisol is similar in both groups (in amplitude and period). This phenomenon is termed *inadequate secretion of cortisol in relation to inflammation*. (b) Allocation of energy-rich fuels follows the circadian rhythm. During the day, fuels are provided to muscles and brain (daytime consumers), whereas during the night energetic substrates are directed toward an activated immune system and growth-related pathways (nighttime consumers). Nightly activation of the immune system stimulates immune/inflammatory responses leading to more disease-related problems in the early morning. Neuroendocrine pathways such as the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) control daytime and nighttime energy allocation via distinct regulators as indicated by the bold red arrows.

of proinflammatory nuclear factor- κ B (NF- κ B) effects. Other studies have shown that glucocorticoids can interfere with the transcriptional activation potential of DNA-bound NF- κ B complexes leading to antiinflammatory effects. These effects appear very early in the turning-on phase of a proinflammatory response (early stimulation of immune cells). The turning-on phase of a proinflammatory reaction is much more vulnerable to immunosuppressants than the turning-off phase. Therefore the regulation of an important proinflammatory factor such as a TNF increase must occur very early because otherwise an overwhelming secretion of this harmful cytokine would occur.

In view of the circadian rhythms and the impact of the timing of immunosuppressive administration on efficacy, there is great interest in exploring timed-release forms of cytokine neutralizers (based on small molecules) or cronobiologic administration of antiproliferative drugs such as methotrexate as a therapeutic modality in RA.^{67,68} Reformulation of old drugs like glucocorticoids (nocturnal hormone) in new circadian drug delivery forms has recently optimized the clinical efficacy and improved immunosuppressant activities in RA.⁶⁶

In a 12-week multicenter, randomized, double-blind trial, 288 patients with active RA were randomly assigned to receive either a modified-release prednisone tablet that released prednisone at 2 AM ($n = 144$) (following the night circadian synthesis of the endogenous glucocorticoids) or an immediate-release prednisone tablet ($n = 144$). The modified-release tablet was taken at bedtime (10 PM) and prednisone was released with a delay of 4 hours after ingestion. This treatment (night available prednisone) was compared with morning administration of immediate-release prednisone as an active comparator and showed significant superiority to the immediate-release formulation.^{66,69}

On the other hand, vitamin D levels show a circannual rhythm with troughs in winter and peaks in summer and demonstrate a significant negative association with clinical RA severity as assessed using the 28-joint

Disease Activity Score.⁶² In addition, the onset of arthritis symptoms during the winter or spring has been associated with greater radiographic disease progression at 6 and 12 months.⁷⁰ Thus seasonality of first symptoms seems to be an independent predictor of radiographic outcome and disease severity, which might be related to the seasonal lack of the immunosuppressive action of vitamin D.⁷¹

In healthy individuals, downregulation of Toll-like receptor 4-mediated production of IL-1 β , IL-6, TNF, IFN- γ , and IL-10 by peripheral blood mononuclear cells was observed only in summer and not in winter (vitamin D effect?).⁷² Because high-dose oral therapy with the vitamin D₃ analogue alfacalcidol exerted a positive effect on disease activity in 89% of 19 patients with RA,⁷³ one can speculate that circannual administration of vitamin D in wintertime can improve the disease status in RA patients. Recent data suggest that calcitriol [1,25(OH)₂D₃] may downregulate proinflammatory cytokine production in activated macrophages in humans by significantly decreasing aromatase activity, especially in an estrogenic milieu such as RA synovial tissue.^{48,74}

CONCLUSION

Clinical observations indicate a strong influence of the neuroendocrine system on immune function in chronic inflammatory and immune-mediated diseases. In addition, these neuroendocrine pathways influence the development of the immune system by interfering with the thymus in that almost all hormones of the HPA and HPG axes support the gradual involution of the thymus. Similarly, hormones of these two axes also hinder B-cell lymphopoiesis, which was demonstrated for 17 β -estradiol in particular. On the other hand, CRH, ACTH, and 17 β -estradiol exert some immunostimulating effects, whereas glucocorticoids and androgens generally suppress immune responses.

The action of the different hormones is influenced by (1) the immune stimulus (foreign antigens or autoantigens) and subsequent antigen-specific immune responses; (2) the cell types involved during different phases of the disease (e.g., T cells, B cells); (3) the target organ with its specific microenvironment; (4) the timing of hormone increase in relation to the disease course (and the reproductive status of a woman); (5) the serum and local concentration of hormones; (6) the variability in expression of hormone receptors depending on the microenvironment and the cell type; and (7) intracellular and extracellular peripheral metabolism of hormones leading to important biologically active metabolites with quite different antiinflammatory and proinflammatory function (common pathway in men and women).

The circadian rhythm of disease-related symptoms with a peak in the early morning hours confirms that the neuroendocrine system has a strong

influence on these chronic immune/inflammatory diseases. The influence is transferred by the circadian undulation of the activity of hormonal and neuronal pathways linking the brain to immune cell activation.

New therapeutic strategies are based on circadian rhythms and generally on a more detailed understanding of the complex neuroendocrine immune system. In addition, circannual therapy with vitamin D might be a new treatment strategy. A new theory explains pathophysiology and disease sequelae as an evolutionarily selected program to allocate energy-rich substrates to the activated immune system. The continuous use of this neuroendocrine program leads to unwanted disease sequelae that have been recognized in recent years. These pathophysiologic considerations can lead to new therapeutic strategies that interfere with cellular energy metabolism, possibly in a circadian or circannual way.

Interpreting the medical literature for the rheumatologist: study design and levels of evidence

■ ROBERT B.M. LANDEWÉ

- Randomized controlled trials are not necessarily the best solution for every clinical question; many relevant clinical questions are better addressed in well-designed and appropriately analyzed observational studies.
- Statistical significance is not a goal *per se*. Statistical testing ideally is only a minor part of the analysis of clinical research, and the merits of a “significant *P* value” are all too often overrated.
- It is very important that trial designers make a clear distinction between trials with a superiority design and trials with a noninferiority design. It is even more important that readers of the trial reports are aware of the differences between the two, and interpret them accordingly.
- Only appropriate communication about the internal and external validity of trials will ultimately result in appropriate implementation of trial data and improvement of patient care.

INTRODUCTION

In medicine there is a strong belief that randomized controlled trials (RCTs) are superior to observational studies. Randomization does provide indisputable strengths, but data show that RCTs and observational studies often arrive at the same conclusion. Furthermore, there are theoretic and practical problems that preclude the acceptance of RCTs as the only source of useful information: (1) RCTs often address research questions that do not serve the main interest of clinicians, (2) many research questions cannot be solved by RCTs, and (3) an RCT has methodologic requirements that should be met to optimally favor its benefits. Large observational studies are frequently considered second rate; however, observational cohort studies are sometimes the only source of data available and can often supply useful information to complement RCTs.

Although the fundamental theory underlying an RCT—and the primary analysis of an RCT—is relatively simple, practical trial conduct faces many potential pitfalls that may eventually result in violation of prognostic similarity and introduce bias. Examples are inadvertent unblinding of a study drug (e.g., if the study treatment is very effective but the placebo is not), unbalanced nonrandom discontinuation (e.g., if the study drug is responsible for adverse drug reactions that cause selective dropout), or simply poor trial conduct or overt misconduct (e.g., if patients do not show up for visits, assessors do not measure outcomes with scrutiny, or at worst, nonexistent or virtual patients with faked response patterns are reported). It is the investigators' responsibility to optimize trial conduct and data collection, to perform a correct analysis of the data, and to transparently describe the process and results of the trial in the medical literature—this is “good clinical practice.” The consumers of these reports, peer reviewers, scientists, rheumatologists, workers in the pharmaceutical industry, regulatory authorities, and others have their own responsibility. They have the obligation to interpret the data carefully by weighing their integrity and importance, unprejudiced with respect to the investigators' interpretations, and to translate trial data into useful, clinically applicable information. This process has gained attention as “critical appraisal,” and the literature provides superb guidance on how to critically appraise the report of an RCT.^{1,2} Medical journals have agreed on guidelines with respect to trial report (e.g., CONSORT guidelines³), thus tremendously improving critical appraisal. Good clinical practice and critical appraisal are applicable to observational

research without prejudice, although the focus may be slightly different. Recently, for example, the checklist for STrengthening in Reporting of OBservational Studies in Epidemiology (STROBE) was published in an attempt to improve the quality of reports in this field.^{4,5}

In this chapter the focus is primarily on methodologic elements that in my opinion are the most important in critically appraising the results of clinical trials and observational studies with respect to application to clinical practice. Because some of these elements specifically pertain to RCTs, others primarily refer to observational studies, and there is also a generic category pertaining to both types of research, three categories of critical appraisal will be discussed: one primarily referring to RCTs, one referring to observational studies, and one referring to both.

LEVELS OF EVIDENCE

During the past decade the accessibility of medical literature has tremendously improved. It is safe to say that the majority of practicing rheumatologists at present can almost immediately get access to (abstracts of) just about every medical study that has been reported in the literature. In addition, meta-analysis and systematic literature review, in which the available literature is weighed and judged in a systematic manner and the data are pooled, have become an art of science. In an attempt to bring some order to the quality of epidemiologic research and consequently to prioritize types of research with respect to methodologic rigor, several scales have been developed. One of the more comprehensive scales (with most differentiation) is the Oxford Centre for Evidence-Based Medicine scale, which applies levels of evidence to five different study scenarios (therapy, prognosis, diagnosis, differential diagnosis, and economic analysis).⁶ In general, such scales rate systematic reviews and appropriately conducted meta-analyses higher than individual RCTs, followed by observational studies and then case series, with expert opinion at the lowest level. Although level-of-evidence scales can be very helpful in prioritizing (the quality of) studies, a note of caution is needed. Frequently, a study is inappropriately rated. An unplanned subgroup observation in the context of an RCT, for example, should not be rated level 1 because the result is not obtained in an unbiased manner (see later), whereas a methodologically weak RCT also does not deserve a rate of 1. Sometimes, “low-grade evidence” is the only kind of evidence that can be obtained, for instance, if the disease under study is very rare or if an RCT is considered unethical. Those who have been involved in the development of guidelines realize that a lot of what physicians do on an everyday basis is based on “expert opinion” and not substantiated by any study at all.

Instead of relying entirely on levels of evidence, readers of the medical literature rather should rate the studies themselves and try to obtain some insight on what the aim of the study is, how the study has been performed, and what the impact of the results should be with regard to their own patients.

RANDOMIZED CONTROLLED TRIALS OR OBSERVATIONAL STUDIES?

A typical RCT investigates whether a new drug, strategy, or intervention is efficacious and safe in comparison to an equivalent treatment or placebo. The trial involves patient selection and randomization before the treatment begins and, thereafter, a predetermined follow-up time to establish whether the primary endpoint (measure of the treatment effect) has been met. The most characteristic feature—and the major advantage of an RCT—is

randomization. Technically, this process divides patients according to all known and unknown prognostically important factors across treatment groups at baseline and thereby creates a situation of similarity with respect to the probable prognosis. In other words, treatment groups are similar in everything except allocated treatment. Prognostic similarity at baseline is important for attributing an observed effect to a particular treatment rather than to an imbalance in an unrelated, but prognostically important factor.

RCTs also have important drawbacks. They might lack external validity or generalizability. Inclusion criteria and exclusion criteria ensure that the trial population is a particular selection of the entire population with a certain disease. An RCT includes patients who are “prone to change,” who might have a high level of adherence to the protocol to ensure retention, or who have a low probability of adverse reactions from comorbidity, comedication, or both. Consequently, such a trial population comprises highly motivated, often educated individuals who have a high level of disease activity but are otherwise healthy. This scenario does not usually appropriately reflect the normal clinical situation.

Another disadvantage of RCTs is their often relatively short follow-up time. There are several trivial explanations, but probably the most important argument is that true prognostic similarity exists only at baseline and becomes increasingly disparate over time. Take, for example, comedication or other coincident interventions. A short follow-up period is methodologically advantageous (see the later section “Internal Validity and External Validity”) but may in rheumatology reflect only a small proportion of the entire duration that a patient is under observation for a chronic disease in real practice. As a consequence, RCTs often use surrogate endpoints rather than those that truly reflect the clinical outcome of the disease. An appropriate example in this respect is the use of bone mineral density as a surrogate outcome measure for fractures in osteoporosis trials. It depends largely on the study question whether an RCT will provide the most appropriate answer. RCTs do provide a reliable impression of the short-term efficacy and safety of drugs in the selection of patients. They do not, however, provide information about an individual patient’s prognosis, long-term results or relevant outcomes, and data about rare events. It is here that observational studies, with many patients and long follow-up, might prove their value.

CRITICAL APPRAISAL I: ISSUES PERTAINING TO RANDOMIZED CONTROLLED TRIALS

Internal validity and external validity

A trial is a rather artificial construct that usually serves one main purpose: to investigate whether a particular treatment is efficacious. In general, elements of trial design, such as selection of patients, sample size, choice of the comparative intervention, and duration of the trial, are chosen in such a manner that the trial can optimally demonstrate a treatment effect, that is, a difference in efficacy between the new treatment and the control intervention. The methodologic rigor of a trial, which is dependent on these elements of trial design, is referred to as *internal validity*.

Understandably, trials often do not resemble clinical practice. Rheumatoid arthritis (RA) trials, for example, frequently include patients with a high level of disease activity, which may form only a minority in clinical practice. The extent to which clinical trial results can be extrapolated to common clinical practice is referred to as *external validity*. External validity is much more diffuse than internal validity. It depends on how the consumer of the data interprets the results, how these results are presented, how convincingly the investigators have argued their message, and how credible they are in the eyes of the beholder. It depends on whether the reader thinks that the data from the trial are applicable to an individual patient in the reader’s own practice. Undoubtedly, external validity will be judged unsatisfactory if internal validity falls short. The opposite is not necessarily true, however. A trial with high internal validity can easily have insufficient external validity. An increasingly common example in RA is an RCT with 1000 patients who have high disease activity that tests a new treatment against the “currently best available disease-modifying therapy for RA” and finds a small, statistically significant difference in favor of the new treatment that is not very clinically relevant. Such a new treatment will probably be approved by drug registration authorities if it is considered safe because it has proven superiority in a well-conducted trial with high internal validity. Needless to say, this effective treatment with doubtful advantage over existing treatments should not be broadly applied in common clinical practice without further consideration (external validation). Readers of trial reports should weigh the balance between internal and external validity: which prevails when one falls short of the other and which elements are important in translating the trial result into clinical practice.

Efficacy versus effectiveness

It is obligatory to be informed about the underlying aim of the trial, which is not necessarily the same as the primary study objective. Drug registration trials under the auspices of the pharmaceutical industry serve a different purpose than do investigator-initiated trials with treatment strategies. The former are often referred to as explanatory or efficacy trials and are characterized by a high level of internal validity, whereas the latter—pragmatic trials or effectiveness trials—more closely resemble clinical practice, often find their basis in questions emerging from clinical practice, and as a consequence have a higher level of external validity.⁷

The results of explanatory trials are frequently very robust and confirm the efficacy of the drug tested beyond statistical doubt but may fall short in terms of clinical significance. Examples are numerous and include any trial that presents the results of a “new drug” tested against placebo or an active comparator.

Effectiveness trials often have a more understandable trial result that is more easily applicable to individual patients, but the results may be biased, for example, by imperfections in blinding and changes in the type and intensity of treatment during the trial. An interesting type of trial that belongs to this group is the *benchmark trial* in RA. The essential characteristic of a benchmark trial is that treatment (type, intensity, or both) is not kept constant during the course of the trial but is dependent on the clinical response of the individual patient (whether the benchmark is met). Such a trial mimics everyday clinical practice very well but is in conflict with the fundamental theory underlying RCTs, namely, that patient groups in a trial are prognostically similar during the trial. The methodologic robustness of the trial is to some extent jeopardized by increased clinical face validity. Readers should have knowledge of these elements because they are relevant for interpreting the results and deciding about their usefulness for application to individual patients.

Superiority trials and noninferiority trials

Textbooks in clinical trial design teach that the underlying null hypothesis should be carefully formulated during the design phase of the trial. The formulation of the null hypothesis, which in theory is the hypothesis that is challenged by experimentation (the trial), tells immediately whether the basic design of the RCT is aimed at proving superior efficacy of a new treatment (the superiority design) or at proving that a new drug treatment is as effective as a comparator drug, for ethical reasons frequently the current standard of therapy (the noninferiority design). The RCTs that we have seen during the past decade in rheumatology most often have had a superiority design, with the null hypothesis being that the new treatment is as efficacious as placebo or a comparator treatment. The design of the trial and the sample size are dependent on a *minimally important difference*, which is determined in advance by the investigators and serves as the basis for calculations of sample size. In rheumatology, many consecutive RCTs have resulted in a number of treatments that have proven efficacy against placebo or against the standard-of-care therapy.

An affluence of effective treatments such as in RA has its other side of the coin. First, there is increasing sympathy for the ethical argument that progress in the treatment of rheumatic diseases should have its consequences for the standard of care in this disease. The immediate implication with regard to trial design is that conventional RCTs with placebo as therapy in the control group will be considered unethical. The more effective the therapy in the control group, the more difficult it is to surpass the effect in the control group with a new treatment—the classic superiority trial will be increasingly unfeasible.

Second, even though we have an affluence of effective drugs for conditions such as RA, there is a knowledge gap with respect to drug efficacy in mutual comparisons. Using previous argumentation, these pregnant clinical questions cannot be solved with classic trial designs. Therefore, we will probably see an increasing number of noninferiority trials in rheumatology in the near future.⁸ Such trials have the null hypothesis that the new drug is inferior to the effective treatment in the control arm and embark on determination of an appropriate *noninferiority margin*. More than the choice of a minimally important difference in superiority trials, the choice of a noninferiority margin in a noninferiority trial is a highly subjective decision that includes elements of efficacy, safety, and cost and can make or break the interpretability of such a trial. It is crucial that readers know about elements of the null hypothesis, such as choices and considerations related to the design type of the trial (superiority vs. noninferiority) and to levels of minimally important difference and noninferiority margin.

Statistical power

Every RCT should technically be able to reject the null hypothesis if the alternative hypothesis reflects the truth—it should have sufficient statistical power. One could justifiably argue that trials with insufficient power should not have been executed. It is unethical to expose patients to potentially harmful drugs if the trial is not able to demonstrate superiority or noninferiority of that drug; if it fills the medical literature with data that are inconclusive and, consequently, poses a risk for misinterpretation and inappropriate application to patient care; and if it is extremely cost-ineffective to conduct trials that do not meet their goals. So it seems obvious that the reader of a trial report should ascertain whether the statistical power was appropriate. Many do not realize that statistical power is more than sample size alone. Although the latter is of most importance, statistical power is, among other factors, dependent on the outcome measure (the responsiveness and discriminatory capacity) and the expected effect size (the anticipated difference between the new treatment and the control treatment). The wording justifying the sample size of the trial provides, to some extent, resolution of the power considerations. In sample size calculations, patient numbers are calculated for a given primary outcome measure with an assumption for its variability, for given values of *beta* (1 – statistical power), and for a pre-defined effect size. Sometimes the anticipated effect size is based on realistic assumptions stemming from previous studies, but all too often an effect is chosen that has no scientific precedent (“20% between-group difference”). Some investigators want 80% statistical power, others choose 90% power as preference, and all too often the reader is left with the impression that convenience outweighs theoretic arguments about power: “the calculation should fit.” Rather than only describing the sample size calculation *per se* (which is often done inappropriately), the trial report should include argumentation for the chosen assumptions, such as the level of the minimal clinically important difference, the noninferiority margin, the level of *beta*, the historic precedents, and so on, and the reader should try to interpret this cautiously.

Intention-to-treat analysis

Every investigator, every trial designer, and every clinician knows about the dogmatic character of the intention-to-treat (ITT) principle underlying the main analysis of a clinical trial. Although occasionally a paper mentions a surrogate of ITT (e.g., “modified ITT analysis”), the definition of ITT is crystal clear. It means that all patient in the trial are considered to belong to the group that they were originally allocated to by randomization, regardless of what has happened to them during the trial. The justification for this somewhat dogmatic principle is that the ITT analysis is the most conservative analysis because it preserves at least the prognostic similarity that was created at baseline by randomization. All other types of analyses, including “modified ITT,” are second rate because they allow retrograde patient selection at baseline. The typical *completers analysis*, for example, includes only patients who have done well with the allocated study treatment and ignores those who have discontinued treatment and may differ from the completing patients in terms of prognosis (prognostic dissimilarity). In fact, completers of an RCT form a selected group of patients and should be considered an observational cohort rather than a trial group (see later).

ITT is not a certificate for an appropriate trial analysis. The trial report should spell out how patients who do not provide actually measured trial data are handled (see the later section “Missing Data”). It should mention how data generated by patients who discontinued the trial medication but showed up at visits are handled. Last but not least, there is no generic means of data manipulation in this regard. For example, considering every dropout to not have changed (improved) in a clinical trial involving RA patients and ACR20 (American College of Rheumatology 20% improvement criteria) as the primary outcome measure is probably conservative because a proportion of these patients will have had a clinical response. However, considering these dropouts as not having changed in a clinical trial with radiographic progression as the outcome measure is all but conservative because it looks as though the dropouts do not exhibit progression, and a trial arm with a high proportion of premature discontinuations may show spurious benefit.

In summary, ITT together with appropriate handling of data, including appropriate imputation, works conservatively in that it tends to reduce a treatment contrast.

Conservatism, however, is not necessarily a guarantee for a more truthful trial result. In a noninferiority trial, ITT may spuriously lead to a conclusion of noninferiority, whereas in truth, unbalanced withdrawal, poor trial conduct, or unintended cointerventions may be responsible for the absence of a difference between treatment groups. An example may clarify this statement (Table 26.1). Suppose that two analgesic drugs (A and B) are compared

TABLE 26.1
Example of intention-to-treat analysis

	Treatment A (n = 100)	Treatment B (n = 100)
Number of patients who discontinued the trial	15	15
Number of patients who completed the trial	85	85
With clinical response	25	20
Number of patients taking rescue medication	10	30
With clinical response	2	20
Response percentages based on:		
Intention-to-treat analysis	25% (25/100)	20% (20/100)
Completers analysis	29% (25/85)	24% (20/85)
Per-protocol analysis	31% (23/75)	9% (5/55)

with respect to their ability to relieve pain in an RCT and that drug A is in truth more effective than drug B (which of course you do not know in reality). The primary outcome measure is the number of patients with a 40% decrease in pain on a visual analog scale. Suppose also that patients take additional acetaminophen if they experience too much pain (“rescue analgesia”). Expectedly, the proportion of patients taking additional medication is lower in group A (the better treatment) than in group B (10 patients vs. 30 patients). Also expectedly, only 2 of these 10 patients in group A needing additional drug experienced a response (the severe cases), whereas 20 of the 30 patients needing additional drug (the milder cases) in group B experienced a response (attributable to comedication). Table 26.1 shows how different types of analysis (ITT vs. per-protocol design) work with regard to response percentages and treatment effect. Keep in mind that in reality drug A is more efficacious than drug B. The unbalanced use of comedication resulted in (only) 5% more responses in group A than in group B if analyzed by ITT. This is a small difference, probably not compatible with a conclusion of superiority of drug A in a trial with a superiority design but easily compatible with a conclusion of noninferiority of drug B in a trial with a noninferiority design. The picture changes, however, if the analysis is repeated on a per-protocol basis. Now, the treatment effect consists of almost 20% more responders in group A than in group B, probably compatible with the superiority of drug A in a trial with a superiority design and incompatible with the noninferiority of drug B in a trial with a noninferiority design: ITT analysis is conservative with respect to concluding superiority of a drug in a superiority design (even if in reality superiority exists). Per-protocol analysis is conservative with respect to concluding noninferiority in a noninferiority design.

Analysis of noninferiority trials is not yet a closed book, but experts are in favor of simultaneously presenting ITT and per-protocol analyses so that readers can judge for themselves. It is always wise to be careful with interpretation if both analyses differ importantly (such as in this example).

Subgroup analyses

The issue of subgroup analysis in clinical trials is controversial. Proponents of subgroup analysis point to its hypothesis-generating potential. Opponents argue that subgroup analysis is irresponsible data mining that involves looking for statistically significant differences by splitting up the trial population into smaller subgroups. Both parties are right to some extent. Subgroup analysis can sometimes help disentangle incomprehensible trial results and can raise attention about new, previously unacknowledged phenomena. However, inappropriate subgroup analysis can also provide spurious results, either by coincidence (multiple testing effects) or by unintended patient selection mechanisms. An example of the latter is as follows: the investigators of an RCT compare radiographic progression in a subgroup of patients with an early clinical response and a subgroup of patients without an early response and find that progression is significantly lower in the first subgroup. This result, however, may easily be confounded by less severe disease at baseline in the favorable subgroup.

It is relevant to some extent to divide subgroup analysis into preplanned and *post-hoc* subgroup analysis. The former refers to the design phase of the trial and includes analyses in subgroups that are of potential relevance, such as the treatment effect in men and women separately or in patients who are rheumatoid factor positive and negative. Importantly and in contrast to *post-hoc* subgroup analysis, the decision to perform and report such an analysis

Fig. 26.1 Results of subgroup analysis of an imaginary clinical trial comparing two treatments (dashed line with squares, treatment A; solid line with triangles, treatment B) in a subgroup with high baseline disease activity and a subgroup with low baseline disease activity. See text for clarification.

cannot be driven by knowing the data. In practice, however, it is often difficult to discern whether a preplanned subgroup analysis is truly preplanned. Methodologically, preplanned subgroup analysis is superior to *post-hoc* analysis only if the subgroups of interest were created by *stratified randomization*, which means randomization within the subgroups. It is hoped that stratified randomization creates prognostic similarity within the strata (a trial within a trial) and, that if performed appropriately, provides sufficient statistical power to detect a meaningful difference within the subgroup.

Usually, subgroup analysis is not performed in subgroups created by stratified randomization. If subgroup analysis is performed and the question of interest is whether a particular treatment performs differently in subgroup X than in subgroup Y, it is important to realize that the analytic translation of this question refers to testing statistical interaction.

Figure 26.1 shows an example of such an interaction. In the first panel, treatment A is less effective than treatment B, both in the subgroup of patients with high disease activity and in the subgroup of patients with low disease activity. The treatment effect is similar in both subgroups: no interaction.

In the second panel, however, the treatment effect is dependent on the subgroup of disease activity. Although treatment A seems to be effective in patients with low disease activity though less effective than treatment B, it seems to be completely ineffective in patients with high disease activity even though treatment B is still effective in this subgroup: interaction. Very often, absence of efficacy in the subgroup of patients with high disease activity is found and reported while the other subgroup is ignored, so it is not clear whether a presumed effect is truly attributable to a specific subgroup. This type of subgroup analysis makes sense only if the interaction is demonstrated and confirmed statistically. The issue of how to statistically test interaction is beyond the scope of this chapter.

In summary, subgroup analysis can be informative, but there are certain rules of play, among which the most important is probably interpretation of subgroup analyses cautiously and with reservation.

CRITICAL APPRAISAL II: ISSUES PERTAINING TO OBSERVATIONAL STUDIES

Types of cohorts

Usually, observational research involves the prospective follow-up of a group of individuals (cohort) with regard to a particular outcome. That outcome can be an event (e.g., death, clinical remission) but can also be a disease activity state over time (e.g., time-averaged disease activity state, mean swollen joint count). The types of cohorts that may be encountered in literature can grossly be divided into two: healthy cohorts and clinical cohorts. It is relevant for the reader of an article to realize what type of cohort is being studied.

Healthy cohorts

Healthy cohorts are large cohorts of individuals who are healthy with respect to the outcome of interest (although possibly not in other aspects).

Frequently, study subjects belong to some group of easily traceable individuals (e.g., nurses or physicians). The outcome of interest is usually simple and unequivocal (e.g., mortality), cohorts are large, and follow-up is typically long. The research question of interest might refer to an intervention but also to a potential risk factor or an exposure. Famous examples of healthy-cohort studies are the Baltimore Longitudinal Study of Aging, the Framingham study, the Johns Hopkins Precursors Study, and the Nurses Health Cohort. Very often and understandably, these large cohorts are used to address multiple different study questions and are sometimes therefore referred to as “multipurpose cohorts.”

Clinical cohorts

Clinical cohorts include patients with one or more features in common who are observed for a definite or indefinite time with respect to one or more primary outcomes. There are several types of clinical cohorts. Inception cohorts include and follow all patients in whom a particular disease is diagnosed (disease duration at baseline = 0). Prevalence cohorts include and follow patients with a particular disease at a certain point in time (disease duration at baseline ≥ 0). Patient registries include and follow patients with a particular disease and a particular feature (e.g., patients with RA who start a particular treatment). The distinction between cohorts and registries is subtle and frequently, but not always relates to the time of follow-up. A cohort generally has a previously defined (limited) follow-up (although this follow-up duration is often adjusted over time); a registry has, in principle, an undefined (unlimited) follow-up duration.

A special form of observational prevalence cohort that is frequently seen in rheumatology is the follow-up cohort of an RCT, the purpose of which is often to investigate whether a particular effect seen in an RCT can be maintained over a longer period. Occasionally, trial arms of the original RCT are preserved during the follow-up period, but often they are not. Importantly, results from follow-up studies of RCTs should not be interpreted as though they have the same scientific rigor as the RCT itself. The prognostic similarity created by randomization exists only at baseline and is increasingly lost over time, particularly when trial blinding is unveiled and patients are asked to continue in a follow-up study. The type of longitudinal bias that might arise is discussed in the next section. One specific limitation of such cohorts with regard to generalizability is that patients in the cohort stem from a clinical trial and reflect a population with relatively severe disease, high disease activity at baseline, and so on. One should keep in mind that relatively mild cases are by definition not included in the cohort, which has implications for the interpretability of prognostic variables derived from such cohorts.

Selection bias

Looking at the characteristics of observational studies as outlined earlier, it is obvious that they are a better reflection of common clinical practice than RCTs are, perhaps with the exception of follow-up studies of RCTs. This is also their major advantage. However, cohorts and registries are not unselected populations. A number of selection mechanisms might influence the interpretation of results, and three well-known examples will be discussed.

Left-censorship bias

Left-censorship bias can occur if patients with particular characteristics are inadvertently excluded from the observational cohort because they are simply not available. Suppose that you want to investigate the relationship between cyclooxygenase-2 (COX-2) inhibitors and cardiovascular morbidity in a database of 10,000 patients, including all prevalent patients with osteoarthritis. The study does not include patients who were at such high risk for cardiovascular death that the outcome (death) has already occurred before entry into the study. As a consequence, the observed mortality rate in this cohort might be an underestimate of the truth, especially if COX-2 inhibitors are particularly dangerous in high-risk patients.

In general, left-censorship bias occurs at formation of the cohort or before the cohort is formed, it refers to selection based on differences in disease severity, and it is important only if severity is related to the outcome of interest. By definition, its influence is difficult to quantify and it is impossible to adjust for left-censorship bias in the analysis.

Right-censorship bias

Right-censorship bias is also known as “selective dropout” or “attrition.” Suppose, in an RCT using a COX-2 inhibitor, that patients at higher risk for adverse gastrointestinal events had a higher dropout rate than did those at low risk. This would lead to a spuriously low rate of adverse gastrointestinal events in the patients who remain in any open follow-up. A type of right-censorship bias that most readers will be familiar with is bias by trial completion, or “completers” bias, which is often seen in follow-up studies of RCTs. Only patients who perceive that their treatment is effective or who tolerate it best (or both) remain in the study, which provides favorable study results for that drug.

Right-censorship bias occurs when the composition of the cohort is determined during follow-up, refers to selection based on differences in disease severity or disease activity, and is important if severity or activity is associated with outcome. Right-censorship bias can be quantified and adjusted for in the analysis to some extent.

Confounding by indication

Confounding by indication refers to the question of which patients begin treatment with which drug. Suppose, in a clinical practice setting, that patients at high risk for gastrointestinal events are initially given COX-2 inhibitors whereas those at lower risk are given conventional nonsteroidal antiinflammatory drugs (NSAIDs). A higher event rate is found in patients treated with COX-2 inhibitors than in those treated with NSAIDs; however, the rate in these high-risk patients might still be lower than it would have been if they had been treated with conventional NSAIDs.

Confounding by indication can occur before as well as after composition of the cohort; it refers to situations in which the severity of the disease determines the choice of treatment, and it is important if treatment and disease severity are both related to outcome. There are techniques that quantify the severity of disease, so it is possible to adjust for confounding by indication.

CRITICAL APPRAISAL III: ISSUES PERTAINING TO RANDOMIZED CONTROLLED TRIALS AND OBSERVATIONAL STUDIES

Generalizability

As argued earlier, the type of patients included in a study is of pivotal importance with respect to interpretation of the trial results. In efficacy trials, statistical power—the probability that the trial confirms the superiority of a new treatment if such superiority truly exists—is of eminent importance. Discriminatory ability and sensitivity to change in the outcome measures are determinants of statistical power. The outcome measures propagated for clinical trials in RA, such as the ACR⁹ and European League Against Rheumatism (EULAR)¹⁰ response criteria, perform best—and have been validated—in patient groups with high levels of disease activity, which is why most efficacy trials include such patients. In the spectrum of patients with RA, however, these patients do not constitute a majority, which may have implications for interpretation of the trial results. It is possible, if not likely, that many RA patients with less active disease do not necessarily need the “new treatment” that tested most effectively in the efficacy trial but can do very well with the comparator drug.

Another discrepancy between observational studies (clinical practice) and RCTs is the paucity of clinically relevant comorbid conditions in RCTs

as compared with clinical practice because patients with relevant comorbidities are usually excluded. Similar reasoning can be followed regarding compliance or, in general, any reason that increases the probability of premature discontinuation, nonresponse, or both.

It is very important when appraising a report of a clinical trial to realize that the patients in the trial do not necessarily resemble individual patients in clinical practice and that such discrepancies may have consequences for translation of the trial results. Study reports should include all necessary information about disease activity, severity, and prognosis (which they often do), as well as information about relevant comorbidity and comedication (which they often exclude), to allow the reader an appropriate interpretation of generalizability.

Missing data

Ideally, RCTs and observational studies should provide complete data. In practice, however, studies without missing data do not exist: patients miss planned visits for whatever reason and do that more frequently than any investigator would consider acceptable; patients withdraw consent, lose motivation, and drop out; patients report adverse events to the investigator, who decides to discontinue the patient from the study; the investigator and patient are disappointed with regard to a drug effect and decide to stop; or a patient moves and gets lost to follow-up. All these examples create missing data. Although the examples given here are very familiar to every reader (and will be considered inherent to clinical practice), the methodology, statistical analysis, and interpretation of the study results do not very well comply with the problem of missing data. It is crucial to realize the issue of missing data before the study starts and to consider scenarios on how to handle missing data. There is not one acceptable generic solution, but by far the worst solution is to entirely withdraw the patient from the analysis. Usually, discontinuation is a nonrandom process, which means that the reason why patients withdraw is somehow associated with disease severity and therefore with the probability of achieving an outcome or a treatment response (confounding). Ignoring these patients means that in a trial, treatment groups cannot be considered prognostically similar anymore, which is probably the most important violation of trial methodology that can be committed, and that in observational studies, the results may be biased by selection.

Data imputation is the only alternative. Imputation means that an imaginary value is attributed to missing assessments so that the patient with missing data remains in the analysis, but the question obviously is what to impute. *Nonresponder imputation* is a popular and conservative means of data imputation in clinical trials with a response measure (e.g., ACR20) as primary outcome variable. It simply attributes nonresponse to every patient who discontinues participation in the trial, irrespective of the reason for discontinuation. *Last observation carried forward (LOCF)* and *baseline observation carried forward (BOCF)* are popular means of imputing continuous data in which the last value or the baseline value that was actually measured, respectively, are imputed as a substitute for subsequent missing assessments. *Worst-case scenarios* impute the worst group value or the value representing the 95th percentile. Imputation of group means or group medians is also used. *Linear interpolation* can be useful if in-between data points are missed, and *linear extrapolation* is used if the expected time course follows an approximately linear trend. Finally, sophisticated computer algorithms (e.g., bayesian, Markov chain, Monte Carlo multiple imputation procedure) exist that use multiple imputation techniques. Discussion of such techniques is beyond the scope of this chapter.

As argued, there is not a single acceptable means of imputation. Nonresponder imputation usually works well if a predefined response is the outcome of interest, and LOCF seems to be a reasonably conservative approach for imputation of missing continuous data in a setting in which treatment should improve a preexistent state (e.g., disease activity, physical function). Linear extrapolation is frequently used to impute missing radiographic data because the natural course of radiographic damage is compatible with worsening and LOCF would result in spurious inhibition of progression. In theory, trial results (i.e., the treatment contrast) should not be dependent on what means of data imputation is used for missing data. The only transparent way of confirming the robustness of the study result is to perform and show sensitivity analyses for the missing data. This means that different means of imputation are performed and the consequences checked with regard to the outcome of interest.

Data interpretation

Probably the most important means of communicating study results is by graphs. A well-designed graph provides far more information than does a table with comprehensive descriptive data, such as means, standard

deviations, and so on. An appropriate graphic representation of the treatment results can provide a good idea about the relative efficacy of a new treatment in comparison to a control drug at first glance. Every reader of RA clinical trial articles will be familiar with the informative bar graph representation of ACR20/50/70 responses per group. More cumbersome is the graphic representation of radiographic progression. The most frequently used Sharp-van der Heijde progression score usually has a skewed distribution, which means that the data are not normally distributed. Very often, a data set of radiographic progression scores includes a high number of zero scores and a relatively low number of positive scores, with a minority of extreme progression scores at the right side of the spectrum. This feature means that the usual parametric descriptive statistics such as means and standard deviations do not appropriately reflect what has actually happened in the group. Medians and percentiles (25%, 75%) do a better job in that respect, but median progression in modern clinical trials of RA is often zero in the intervention and the control group, whereas progression is statistically significantly different. Recently, probability plots have been proposed to fill in this gap in communication.¹¹ A probability plot shows every individual change in score per trial arm; it is ordered from the lowest through the highest observed value and is plotted against its cumulative probability. By superposing the plots of the trial arms in one graph, it is clear at first glance how the groups have performed with respect to radiographic progression.

Tabulation of data is important for several reasons: (1) to underscore the authors' conclusions and make them transparent to critical appraisal, (2) to make additional inferences for data interpretation (examples are calculations for the *number needed to treat* and *effect sizes* for researchers interested in the performance of outcome measures), and (3) as a source for the meta-analyst. It is critical that the authors of a trial report realize that their data may be used for several scientific purposes, and they should provide sufficient information. It is difficult to give exact guidelines because the prerequisites are different for different outcome measures, but a few examples may help. When the ACR response is used as an outcome measure, it is crucial to report not only proportions but also crude numbers (numerator as well as denominator). When continuous outcome measures (e.g., swollen joint count, disease activity state) are reported, data about status, as well as change, should be provided as means and appropriate standard deviations (rather than standard errors of the mean), in addition to the actual number of patients used in the analysis. When distributions of continuous outcome measures are overtly skewed (e.g., radiographic progression scores), the investigators should present not only means and standard deviations but also medians and key percentiles (e.g., 25th, 75th). With regard to reporting on radiographic progression, there is consensus that—in the interest of the meta-analyst—logarithmically transformed progression scores should also be reported in the tables.¹²

The statistical test

The main goal of statistical analysis in the report of a trial or an observational study is to challenge the null hypothesis or, in other words, to find probabilistic support for a difference observed between treatments (trial) or for a (predictive) association (observational study). A second aim of statistical testing is to determine the robustness of a demonstrated effect.

In flagrant contrast to what is often done, in reality, statistical analysis should take only a modest place in the report of a study. However, many authors cannot resist the attractiveness of " $P < .0001$ " and build their article around the statistical test result rather than the opposite. Unfortunately, many of these authors are unable to reproduce the correct interpretation of $P < .0001$ and counter critical questions about the relevance of the effect with, "It is highly statistically significant, though, isn't it?," thus implying that the effect is clinically important.

The P value is a probability, namely, the probability that even if it is assumed that the null hypothesis is correct, it is nevertheless rejected. This sentence is comprehensible only if one realizes that the clinical trial one is looking at is just one (random) example of many, let us say 1000, imaginary similar trials. Whoever accepts this will also accept that all 1000 imaginary trials will have 1000 different results. The majority differ only slightly, a few will have more deviant results simply by coincidence, and a very few will even have extremely deviant results in either direction, whereas in truth the difference should be zero! In theory, such differences could be of such a magnitude that they lead to rejecting the null hypothesis. We talk about erroneous rejection of the null hypothesis, or a type I error. The P value is the probability of a type I error. $P < .0001$ means that there is very, very small chance of a type I error. It could be said that the result is very robust and that such a P value adds to the credibility of the trial (internal validity). It does not say that the difference that was found is a relevant difference or that an effect is meaningful. Current efficacy trials are often so powerful in

Fig. 26.2 Treatment effects and 95% confidence intervals of three potential scenarios (A, B, and C) for an imaginary clinical trial comparing treatment A and treatment B. See text for clarification.

statistically underscoring small differences that very good P values can be obtained with treatment effects that are negligible when considered in the context of patient care. So, statistically significant does not imply clinically relevant. The opposite is also true: not statistically significant does not mean not relevant or in other words, "the absence of evidence is not the same as evidence of absence (of a meaningful effect)," a statement referring to type II error (see later).

The second aim of statistical analysis is to determine how robust the trial results are. Actually, one is interested in the implications with respect to the size of the treatment effect. Usually, a 95% confidence interval (CI) is used to describe the bandwidth for estimates of the treatment effect. Elaborating on the discussion about P value, the 95% CI is best understandable by imagining that a particular trial is done 1000 times. Ninety-five percent of the time the trial result (the estimate of the treatment effect) will lie between the limits of the 95% CI, but 5% of the time the treatment effect will take a more extreme value. The relationship between P value and 95% CI is further clarified in Figure 26.2. Suppose a clinical trial in RA patients with two treatment arms (A vs. B) and (improvement in) disease activity state as the outcome measure. Three possible treatment effects are plotted in a diagram that a reader of meta-analyses may be familiar with. The zero treatment effect reflects the level of equivalence. All three scenarios represent a trial result in which treatment B is better than treatment A (more improvement in disease activity state with B than with A). The P values are presented per scenario. The arrows represent the 95% CIs around the mean improvements in disease activity state. Note that the 95% CIs of scenarios A and C lie entirely to the right of zero. Both treatment effects are statistically significant ($P < .05$); the null hypothesis of "no difference" is rejected. Note that the 95% CI in scenario B crosses zero. The treatment effect is not statistically significant ($P = .05$); the null hypothesis is not rejected. Note also that notwithstanding a *smaller* treatment effect in scenario C than in scenario B, the treatment effect in C is statistically significant, as represented by a narrower 95% CI. We say that the trial result is more *precise*. It is the combination of statistical information and information about the preciseness of the treatment effect that makes 95% CIs such attractive tools in clinical trials. To improve information exchange and interpretation of trial results, it is almost mandatory to present 95% CIs around the mean treatment effects and not only P values. As with many generic rules, the balance occasionally dips to the other side: it is not particularly useful and often confusing to present 95% CIs of variables not related to treatment effects (or related to hypothesis testing). An example is the presentation of 95% CIs around the mean 28-Item Disease Activity Score (DAS28) at baseline.

CONCLUSION

In this chapter a wide array of points to consider in the critical appraisal of RCTs and observational studies have been addressed. Emphasis is placed on issues referring to external validity or generalizability because that is what most rheumatologists need to know. As mentioned in the introduction, the choice of issues addressed is subjective and the chapter is by no means intended to cover everything that is important in appraising study data.

It is hoped that the points raised will increase awareness of the importance of the interplay between the clinical investigator responsible for the study report and the consumer of the data, often the clinician, who has to decide about application of the study results to the area of clinical medicine, which affects individual patients. Only appropriate communication in this area will ultimately improve patient care.

Ethics in clinical trials

■ C. RONALD MacKENZIE ■ STEPHEN A. PAGET

- The objective of clinical research is the acquisition of generalizable knowledge to increase understanding of human biology or to improve health.
- Research subjects may be placed at risk for the good of others.
- An ethical framework has been developed to ensure that research subjects are not exploited and are treated with respect.
- Ethical challenges vary according to the phase of development of the experimental therapy.
- Conflict of interest is a multifaceted challenge in the modern age of medicine.
- Two cases illustrate the ethical issues in drug research involving human subjects.

The objective of clinical research is the acquisition of generalizable knowledge to increase understanding of human biology or to improve health. Although the participation of human subjects is required to achieve these ends, the attainment of the goals of clinical research does not ensure benefit to those who participate. Indeed, it is self-evident that the research subject may be placed at some risk for the good of others, a reality at the core of the ethical dilemmas in human subject research. It is therefore incumbent on those who formulate, conduct, and report such research that their work adhere to the highest standards. This chapter reviews the ethical dilemmas arising in the research setting and presents principles that should guide this activity.

GENERAL ETHICAL PRINCIPLES

Extensive literature and experience serves to inform the philosophical and practical paradigms that guide current human subject's research.¹⁻⁷ Theoreticians interested in this area have looked to the field of moral philosophy and ethical theory to derive principles that provide a foundation for ethical judgments concerning research involving human subjects.⁸ Rooted in the Nazi experimentation revealed in Nuremberg, these efforts have been bolstered by a number of seminal documents beginning with the *Nuremberg Code* (1947),⁹ the *Declaration of Helsinki* (1964),¹⁰ the *Belmont Report* (1979),¹¹ the *International Ethical Guidelines for Biomedical Research Involving Human Subjects*,¹² and most recently *Guidelines for Good Clinical Practice for Trials on Pharmaceutical Products* of the World Health Organization.¹³ Malfeasance and ethical lapses typified by the Tuskegee study have also provided a potent stimulus for change.^{1,2,14} Ethically designed and conducted research now rests on principles articulated in these foundational documents. The *Belmont Report*, a particularly influential statement in the current era, added the notions of respect for persons, beneficence, and justice to the enduring principle of informed consent established in Nuremberg over 30 years before. Indeed, these core ethical tenants provide the foundational elements guiding the current regulation of human subjects research.

WHAT IS ETHICAL RESEARCH?

A useful framework developed by Emanuel and colleagues¹⁵ incorporates seven requirements whose purpose is to ensure that research subjects are not exploited and are treated with respect (Table 27.1). The ethical

considerations inherent in these requirements can be framed in the form of the following questions^{6,15}:

1. Does the anticipated societal and scientific value of the research justify the resources required to conduct the research?
2. Does the research employ valid scientific methodology and is it practically feasible?
3. Is the selection of subjects fair and equitable?
4. What potential harms and risks are imposed on the research subjects? Are the risks minimized? Are the potential societal benefits in proportion to the risks imposed on the participants?
5. Has the study undergone independent review?
6. Is informed consent sought from the research subjects?
7. Are there safeguards to ensure respect for research subjects during their participation in the research?

The intent of these requirements is to provide a methodology for the evaluation of the ethics of clinical research.

ETHICAL CONSIDERATIONS IN CLINICAL TRIALS

In the setting of drug trials, the traditional stages (phases 1 to 4) of scientific development present phase-specific ethical challenges^{3,5} that vary in importance as a drug (or device) works its way through the approval cycle.

Phase 1 trials represent the first testing in human subjects. Typically small in size, these trials usually, but not always, involve healthy volunteers. Safety and toxicity in contrast to efficacy are the primary concerns, and for this reason informed consent, risk-benefit, and scientific validity are particularly relevant. Participants receive no benefit—indeed they may experience significant adverse consequences—and hence are dedicating themselves to the “greater good.” Phase 2 clinical trials include more affected subjects and thus may include efficacy as an active endpoint but have similar ethical considerations. Phase 3 trials involve not only larger numbers of patients but also an ever-widening range of participants, which brings the ethical construct of fair subject selection to the forefront. Clinical trials at this stage of development focus on efficacy and safety. With both phase 3 and 4 clinical investigations, the latter conducted after the drug has been approved, respect for enrolled subjects becomes a primary consideration raising concerns such as allowing voluntary withdrawal from participation, protecting privacy, and informing subjects of new risks and benefits as well as the results of the research. Phase 4 clinical trials are the postmarketing investigations conducted by the pharmaceutical industry. Although a subject of some criticism, such studies are considered justified because they provide important data on serious but low-prevalence adverse events.

RANDOMIZED CONTROLLED TRIALS

Randomized controlled trials (RCTs) remain the gold standard methodology for the demonstration of efficacy and safety in the development of new therapies. This format is defined by a number of design characteristics including randomization, blinding, and the comparison of two (or more) interventions, used to demonstrate therapeutic equivalence or superiority of one treatment over another. Despite its advantages, this research design presents a unique spectrum of ethical challenges for the investigator.^{3,15} These include such matters as the treatment versus research distinction (often referred as the *therapeutic misconception*),¹⁶⁻²⁰ equipoise (the lack of convincing evidence that one intervention is superior to another),^{6,21} the choice of comparators (the use of a placebo is important),^{3,5,22-25} randomization (which does not allow for autonomous preferences in treatment),³

TABLE 27.1

Ethical requirements for ethical research

REQUIREMENT	ETHICAL VALUES
1. Social or scientific value	Scarce resources, nonexploitation
2. Scientific validity	Scarce resources, nonexploitation
3. Fair subject selection	Justice
4. Favorable risk-benefit ratio	Nonmaleficence, beneficence, and nonexploitation
5. Independent review	Public accountability, minimizing influence of potential conflicts of interest
6. Informed consent	Respect for autonomy
7. Respect for potential and enrolled subjects	Respect for autonomy and welfare

blinding,³ and the sharing of preliminary information. Each of these ethical challenges warrants commentary.

Levine defines *practice* as activities “designed solely to enhance the well-being of an individual patient,” whereas the intent of *research* is to contribute to a base of knowledge that can be generalized to all those who suffer from the disease under investigation.²⁰ In the setting of clinical research, this distinction is easily blurred, especially when existing treatments for the disease in question are unsatisfactory or when the proposed new treatment is highly innovative. In these circumstances, research subjects often fail to appreciate the difference between research and treatment, a phenomenon known as *therapeutic misconception*.¹⁶⁻²¹ The way to resolve this dilemma is to ensure that research subjects understand that the purpose of clinical research is to produce generalizable knowledge, regardless of whether or not they derive benefit from their participation in the study. Five dimensions have been suggested as safeguards to ensure the subject’s comprehension of the research (Table 27.2).²¹ Thus in contemporary medicine, where practice and research may coexist, it is virtually instinctive that physicians might wish to employ pioneering therapy despite a lack of formal validation. In such circumstances, the line that demarcates research from treatment can be easily breached, which reinforces the need for attention to these ethical issues.

Of the defining principles, the physician’s duty to the individual patient remains a central doctrine. Dating back to Hippocrates, this notion is deeply embedded in how medicine expresses its professionalism. This fiduciary duty is communicated primarily through the clinical transaction, a patient-centered endeavor that relies on physician-based attributes often characterized as virtuous.²⁶⁻²⁸ Against this backdrop, there is the contrasting duty of the researcher—the promotion of human welfare through the rigorous application of the scientific methods (research). An important and problematic feature of the RCT arises from the randomization, a method in which treatment is apportioned by chance rather than by physician recommendation. A patient’s needs and values thus become subverted, even sacrificed, for the greater good of others. An approach to resolving this dilemma is the concept of *equipoise*,²⁹ which requires a researcher to have no justifiable reason for preferring one treatment over another in a clinical trial. *Clinical equipoise* simply expands this concept. Instead of being a requirement that the treatments exist in exact balance (the researcher would have no preference), *clinical equipoise* is based on an honest disagreement among knowledgeable professionals concerning the superiority of one treatment. For this reason an RCT can be considered permissible because it shifts the responsibility from the researcher to the greater community of physicians.

Another problematic aspect of clinical trials is the use of placebos. When new therapies are being examined, or when current treatment is ineffective or unsatisfactory, the use of placebos does not raise ethical concern. However, a problem arises when new therapies are being compared with established treatment. The *Declaration of Helsinki* states that the “benefits, risk, burdens, and effectiveness of a new method should be tested against those of the best current . . . methods.”¹⁰ The Food and Drug Administration, however, has generally been supportive of the use of placebos because such studies may produce more “purified” knowledge.²² One approach toward reconciliation is that the burden of proof lies with those who propose depriving patients of standard care.²² Alternatively, a middle ground has been advocated²⁵ in which the *placebo orthodoxy*, which promotes the use of placebos based on methodologic considerations, is contrasted with an *active-control orthodoxy* in which placebos are viewed as sacrificing the rights and welfare of patients in the name of scientific rigor. For example, in situations in which life-saving therapy is available, placebo-controlled studies are *prima facie* unethical. The justification for placebos becomes blurred in conditions in which

TABLE 27.2

Dimensions of research that should be understood by research subjects

1. Scientific purpose

Clinical research is designed to produce generalizable knowledge and to answer questions about the safety and efficacy of intervention(s) under study to determine whether or not they may be useful for the care of future patients.

2. Study procedures

Participation in a trial may involve procedures or tests, in addition to the intervention(s) under study, that are intended only or primarily to generate scientific knowledge and that are otherwise not necessary for patient care.

3. Uncertainty

For intervention(s) under study in clinical research, there often is less knowledge and more uncertainty about the risks and benefits to a population of trial participants than there is when a doctor offers a patient standard interventions.

4. Adherence to protocol

Administration of the intervention(s) under study is typically based on a strict protocol with defined dose, scheduling, and use or avoidance of concurrent medications, compared to administration of standard interventions.

5. Clinician as investigator

Clinicians who are in health care settings provide treatment; in a clinical trial setting, they are also investigating safety and efficacy of an intervention.

From Henderson GE, Churchill LR, Davis AM, et al. *Clinical trials and medical care: defining the therapeutic misconception*. *PLoS Med* 2007;4:1735–8.

effective treatments do exist but some potential for harm may arise as a consequence of using a placebo. In these circumstances, compelling methodologic advantages must exist. Examples of such conditions include those with high placebo response rates; those with a waxing and waning course or frequent spontaneous remissions; those for which existing therapies are only partly effective or have produced serious side effects; and those for which the low frequency of occurrence means that an equivalency trial would have to be so large as to compromise enrollment and completion of the trial.²⁵ Many of these characteristics are germane to chronic rheumatic diseases, osteoporosis being a good example.

With the advent of effective therapies for the treatment of osteoporosis, specifically the prevention of fracture, the ethical implications arising from the use of placebos have sparked considerable controversy.³⁰⁻³² The question raised is whether individuals who are highly susceptible to osteoporotic fracture should be enrolled in a placebo-controlled clinical trial. Various approaches to this ethical conundrum include enrolling only patients who have no fracture history or, alternatively, patients who have experienced side effects or failed to show a response to current therapy. Most clinical trials involving this condition employ an add-on approach in which the nontreatment group receives calcium and vitamin D. Methodologic solutions have been considered including the use of noninferiority and superiority trials with the placebo group replaced by a group receiving established therapy.³³ Although this may seem to solve the ethical problem, such trials require much larger numbers of participants to demonstrate a reduction in fracture. In addition to the logistical and cost implications, there is also the observation that such trials, given their larger size, ultimately result in more study subjects’ developing fractures over the study period than if a placebo arm had been employed.³⁴ Thus one ethical dilemma is simply replaced by another. Last are the studies that employ various biomarkers of bone turnover as fracture surrogates.³⁵ This approach reduces the number of study participants but is suboptimal, because it does not directly address the most important clinical endpoint (fracture).

Other methodologic features of the RCT also raise ethical concerns. For instance, randomization is usually performed blinded, either single blind (subjects do not know what treatment or intervention they are receiving), or double blind (neither subjects nor investigators know the treatment or intervention). Random assignment and blinding minimize bias and enhance validity. Such procedures are not necessarily compatible with the patient’s best interests or desires, however, nor do they respect the subject’s autonomy.⁵ Two ethical concerns are readily apparent: (1) preferences and information concerning what intervention the subject is receiving is necessary for autonomous decision-making; and (2) information pertaining to which intervention the subject is receiving may be important in the assessment of adverse events or in the setting of medical emergency. Informed consent

addresses the first concern. Providing the appropriate safeguards concerning adverse events, however, requires specification in the research protocol of the conditions, thresholds, and consequences of breaking the code (unblinding the study). A related ethical problem is the sharing of information as it accumulates in a clinical trial, because the risks and benefits of the study therapy may change and thus alter equipoise. Study monitors and independent data safety monitoring boards make decisions regarding the early study termination, thus taking the decision away from the investigator. In the context of international research, a more recent problem is the investigator's (and sponsor's) obligation to ensure ongoing access to the investigational therapy to study subjects upon completion of the clinical trial.^{5,36}

Another recent phenomenon of relevance to clinical trials is the role of contract research organizations (CROs) in drug development.³⁷ CROs are commercial organizations that, as independent contractors, offer clients (usually drug companies) a wide range of pharmaceutical research services in the path of drug development. They offer an important outsourcing function to the pharmaceutical industry, which provides cost savings while bypassing the academic medical center, the traditional (and possibly safer) site for the conduct of clinical trials. CRO-industry revenues have grown dramatically since their inception in the early 1990s.³⁷ Problems such as the preferential enrollment of the economically disadvantaged (through pretrial monetary inducements), "backloading" payment approaches in which the largest payments are made to study subjects at the end of the trial (which inhibits patients from terminating their participation), disquiet pertaining to the comprehension of non-primary-English-speaking subjects (which raises concerns regarding informed consent), inadequate monitoring of adverse events, and concerns about the depth, diversity, and medical knowledge of the workforce that makes up the CRO. Whether or not this model, premised mainly on the desire to reduce costs, compromises ethical oversight remains open to question. Further uncertainty exists with respect to the role and scope of the regulatory mechanisms that oversee the activity of the CROs—that is, do these entities answer to the regulatory agencies responsible for monitoring clinical trials (a mandated requirement for academic medical centers) or to the drug companies that hire them? Few data exist on the degree to which clinical trials involving the rheumatic diseases may have been affected by the CRO phenomenon. However, reliance on this model remains strong and this practice is likely to grow.

CONFLICT OF INTEREST

The term *conflict of interest* encompasses a spectrum of behaviors and actions involving personal gain, usually but not always limited to financial benefit.³⁸⁻⁴¹ Arising over the last two decades from the complex relationships among industry, investigators, and the academic institutions where they are employed, such conflicts raise a variety of ethical issues. That financial and other inducements might influence, and at times overpower, professional judgment comes as no surprise given the pressures accompanying modern life, yet the circumstances and determinants of such behavior are not fully understood. Barnes and Florencio conclude that conflict of interest increases as the value of the secondary interest rises, as professional judgment becomes more specialized and less amenable to supervision, as the decision-making process becomes less transparent, and when there is a long-standing relationship between the participants.⁴² It is well documented that financial and other incentives influence physicians in the clinical environment.⁴³⁻⁴⁵ Although their influence in other arenas of academic medicine may be less appreciated, such influences are pervasive and affect virtually every corner of the academic medical enterprise: physician-industry interactions, investigator-industry relationships, and the academic center itself. Journal publication and continuing medical education likewise are not immune.^{46,47}

Academic institutions have attempted to manage these conflicts. Initially, simple disclosure—for example, of outside financial interests—was considered sufficient. More recently institutional committees review reported conflicts and on occasion require the divestment of equities, the termination of consulting relationships, and the imposition of methods of monitoring. Medical journals have also followed suit, requiring disclosure and implementing other methods such as the rejection of medical reviews by those believed to have conflicts of interest.⁴⁶ Despite these safeguards, breaches are often seen, which supports the need to be ever vigilant.

CASE STUDIES

Modulation of immune responses with biopharmaceuticals such as the monoclonal antibodies (mAbs) has become an important therapeutic strategy for the autoimmune diseases. Because many of these new therapies have

potentially significant toxicities, patient safety and the ethical considerations arising in the context of clinical trial participation will remain at the forefront of the effort to find more effective treatment for this disease. As examples illustrating some of the important ethical considerations arising in this research setting, two recent clinical trials involving such agents are relevant. The clinical details of these cases are summarized in Boxes 27.1 and 27.2.

As a consequence of the experiences in these trials, both protocols have undergone intense scrutiny by the lay press^{48,49} and the scientific community,^{50,51} an assessment that has included an examination by the National Institutes of Health (NIH) Recombinant DNA Advisory Committee and the European Medicine Agency (EMA).⁵² Numerous questions have arisen: Was the science underlying the proposed therapy flawed? What factors or conditions associated with each clinical trial contributed to the outcome? Were the patients adequately informed about the risks of participation? Were the patients sufficiently protected against these risks?

An ethical analysis of these events begins with the informed consent. Under the current guidelines for research participation in the United States, all research subjects must be informed of the risks and the benefits of their participation in a research study, a requirement fulfilled by the process of

BOX 27.1 CLINICAL CASE

The patient was a 36-year-old white female enrolled in an open-label phase 1/2 clinical trial (safety/efficacy study) of a genetically engineered adenovirus encoded with a tumor necrosis factor receptor construct under development by a biotech company as an intra-articular injection for rheumatoid arthritis (RA). The patient had developed RA 15 years before her enrollment, had previously been treated with etanercept (2002 to 2004), and at the time of her recruitment to the study had been managed with adalimumab, methotrexate, and prednisone. She previously had surgery on her toe but not her knee, although she had been treated with multiple (10) knee injections of corticosteroids. Randomly assigned to the highest-dose group, she received her first dose of the study drug on February 26, 2007, without incident. Her second intra-articular injection was administered on July 2, 2007, and on the same evening the patient developed fever and diarrhea. Due to the persistence of the fever, Levaquin was prescribed (July 5, 2007), but over 48 hours she remained febrile (40° C) and was experiencing nausea and vomiting. By July 9, 2007, her knee had become tender, and she was tachycardic, had a white blood cell of 29,000/mm³ (predominantly lymphocytes) and exhibited mild liver function abnormalities. Her fever persisted despite aggressive antibiotic therapy, and subsequently (July 16, 2007) her liver function was further deteriorating, she remained febrile, and the hemoglobin level was noted to be dropping to a low of 4.6 g/dL. Hypotension and respiratory distress ensued, and she was transferred to another center.

By July 19, additional laboratory and radiologic testing revealed a coagulopathy, retroperitoneal hemorrhage, and further deterioration in liver function. At this time the question of liver transplantation was raised but dismissed. Serologic tests for herpes simplex virus 1 showed negative results, as did nasopharyngeal cultures. On July 19 a liver biopsy was performed; the biopsy specimen revealed small areas of acute necrosis and inflammatory lesions and tested positive for *Histoplasma*. Her deterioration continued, and she expired on July 24, 2007. An autopsy revealed disseminated *Histoplasma capsulatum* involving all organs without granuloma (a feature typical of histoplasmosis in the immunocompromised), a large retroperitoneal hematoma, and a minimal swelling of the knees.

BOX 27.2 CLINICAL CASE

Six healthy young male volunteers were enrolled in a phase 1 study of the safety of TGN1412, a superagonist anti-CD28 monoclonal antibody that directly stimulates T cells. Within 90 minutes of receiving a single intravenous dose of the drug, all six volunteers developed a severe systemic inflammatory response secondary to the rapid induction of proinflammatory cytokines. Patients reported headache and myalgia and developed nausea, diarrhea, vasodilatation, and hypotension. Over the ensuing 24 hours, all patients became critically ill with diffuse pulmonary infiltrates, renal failure, and disseminated intravascular coagulation. All patients were admitted to the intensive care unit, where they received aggressive supportive therapy including dialysis, high-dose intravenous corticosteroids, and an anti-interleukin-2 receptor antagonist antibody. Prolonged shock and respiratory distress syndrome developed in two patients, who required intensive support for 8 and 16 days, respectively. All patients ultimately survived.

informed consent as discussed earlier.⁵³ Three primary elements support this requirement: information, comprehension, and voluntariness. Once these elements are achieved, the subject's authorization is sought.^{11,53} Information provided to the research subject should be adequate to explain the rationale for and the procedures involved in the study and should meet a *reasonable volunteer* standard. To do this, the investigator may need to consider factors such as the subject's age and educational level, and other barriers to communication such as language. Informed consent continues throughout the subject's participation in the research.

There have been indications suggesting possible problems with respect to the informed consent process in one of the cases described (see Box 27.1). For example, it has been reported that the subject participated in the clinical trial because of a perceived benefit, primarily the alleviation of her knee pain.^{48,49} This problem, an example of *therapeutic misconception*, has been discussed earlier. Such beliefs are strong inducements to participation and have to be adequately tempered by the primary investigator through a thoughtful, considered process of informed consent. Statements such as "You cannot expect to benefit directly from your participation in this study," so often found on consent forms, are not sufficient to mitigate the problem of therapeutic misconception.

Another important consideration relates to the prestudy risk assessment of the developers of the drug and the primary investigators. Although this subject's death is not believed to have been a direct consequence of the adenovirus vector employed to deliver the anti-tumor necrosis factor medication, the patient's immunosuppression, a consequence of the totality of her therapy, as well as the risk of histoplasmosis in a patient living in an endemic region for this condition may not have been sufficiently appreciated by the investigators.^{54,55}

Concerns pertaining to the ethical oversight of this investigation are compounded by the circumstances of its approval. Ethical review was conducted by an independent institutional review board (IRB), one unaffiliated with an academic medical center. Two issues are raised in this context. The first is the quality of scientific review given the complexities of therapy in this disease setting. Was there sufficient rheumatologic, immunologic, and infectious disease expertise on the IRB to adequately assess the potential for adverse outcomes with this new therapy? The second concern pertains to the for-profit nature of this IRB. Could the approval process have been influenced by circumstances in which the IRB was being paid directly by the company seeking approval for the drug?

In this study a third issue, coercion, is also of concern. The study sponsor had agreed in principle to the use of a neutral party in the recruitment of patients, a protocol that was not employed.⁵⁶ Indeed the research subject was approached directly by her rheumatologist, a practice that may place undue influence on the patient to agree to enroll in the study. To reduce this form of influence, the NIH recommends that physicians not recruit their

own patients into clinical trials they are conducting. In circumstances in which this cannot be avoided, it has been suggested that an impartial third party explain the study and obtain informed consent.⁵⁷ This practice is particularly relevant in studies involving novel therapies that are deemed risky and in circumstances in which the individual's condition is not life threatening, and is especially of interest in studies in which the investigator has a financial interest (as was the case in the rheumatoid arthritis [RA] trial discussed here).

A final concern has to do with the assumption of risk. As in the case of an earlier and now well-documented study involving gene therapy with fatal consequences,^{58,59} the RA study subject had relatively well-controlled disease with standard therapy. Thus the degree of assumed risk may have been out of proportion to the potential benefit, which provokes concern in general as to which subsets of diseases should even be considered for innovative therapies that employ emerging technologies.⁵⁶

In the second example (see Box 27.2), the investigation was a phase 1 study of the safety of a novel immunomodulatory therapy using healthy volunteers. In phase 1 investigations the ethical accountability to the (healthy) study participant is especially high, a responsibility magnified by the difficulty in quantifying risks. Indeed, one of the major impediments to drug development in this arena (mAbs) is the risk of adverse immune-mediated reactions in humans that include immunosuppression, autoimmunity, and, in the case presented, cytokine storm, a topic extensively reviewed recently.³² Dosing for such "first-in-human" clinical trials is based on preclinical safety studies, primarily in nonhuman primates, combined with *ex vivo* studies. Dose selection nonetheless remains challenging because of differences between the primate and human systems, species selection, scientific considerations pertaining to the receptor model employed, calculations based on what is known as the *minimal anticipated biological effect level* (MABEL), and a number of additional considerations relevant to mAbs and their pharmacology and immunology.⁵² The TGN1412 experience, coupled with a growing science pertaining to safer dosage predictions in mAbs therapy, should have addressed this important safety consideration. Although these challenges will require scientifically based solutions, the problems associated with this inexact science just compound the ethical challenges.

An important practical matter arising in this study was the decision to administer the drug to all six participants virtually simultaneously. Clearly, had the administration of the drug been performed in a sequential fashion, thus allowing for observation of each patient individually, fewer of the six study participants would have been subjected to the life-threatening adverse effects of the study drug. This methodologic caution has obvious ethical implications concerning the safety of the study participants and appears to have been recognized in the recently published EMEA guidelines concerning first-in-human clinical trials.⁶⁰

CLINICAL BASIS OF
RHEUMATIC DISEASE

28

History and physical examination

■ ANTHONY D. WOOLF

- History taking is the most important skill in rheumatology.
- The physical examination is pivotal in confirming the cause and effect of musculoskeletal problems.
- Assessment of the musculoskeletal system should form part of any general medical examination.
- The consultation involves a patient-centered phase for the patient's story; a physician-centered phase to clarify the story by interrogation and examination; and an interactive phase during which the patient and physician discuss their concerns, findings, conclusions, and plans.
- The consultation must meet the expectations of the patient.
- Musculoskeletal conditions cause a broad range of problems that need to be assessed by a multidisciplinary team to develop an appropriate plan of management.

INTRODUCTION

Musculoskeletal complaints are among the most common symptoms, and their cause and effect need to be established. Physicians evaluating such patients need to characterize the problem and its impact, establish the cause, and develop a management plan. If unable to identify the cause, physicians must at least be able to describe the abnormality and recognize whether it is important and requires a more skilled assessment. When the person is reviewed, the physician must be able to assess response to treatment and be able to recognize the lack of expected response. Musculoskeletal conditions are also frequent comorbid conditions that need to be identified and treated.

Many common musculoskeletal problems can be managed effectively in the community by the primary care team, but other less common or more serious problems will require specialist management, often within the context of a multidisciplinary team. Different competencies are needed for these different levels of care. All physicians should be able to recognize an abnormality of the musculoskeletal system and whether it is important by being able to perform a screening assessment in combination with basic knowledge of musculoskeletal conditions. More expert management will require greater competency in clinical assessment and more detailed knowledge of the possible causes; such an assessment will be made by a specialist physician (rheumatologist).

In this chapter a basic screening assessment of the musculoskeletal system is described that is appropriate as part of a general examination to identify whether any abnormality is present. A more detailed evaluation of a person with a musculoskeletal problem is also presented. From such assessment the syndrome that the person is complaining of should be identified, and with appropriate knowledge and investigation, a differential diagnosis should be possible.

SCREENING ASSESSMENT

Musculoskeletal conditions should always be sought by routine screening as part of any general history and examination. Once an abnormality has been identified, a more detailed assessment is necessary. This screen takes only a few minutes. It has been validated in a general medical setting and within undergraduate training.¹

Screening history

The common symptoms of any musculoskeletal condition are pain, stiffness, and limitation of function. Joint disease is often associated with swelling. Sensitive functional tests are (1) the ability to dress without difficulty, including socks and shoes, which is a complex activity that uses both the upper and lower limbs, and (2) the ability to ascend and descend stairs without difficulty, which is sensitive in detecting abnormality in the lower limbs. The following screening questions will quickly establish the presence or absence of major musculoskeletal problems.

- Do you suffer from any pain or stiffness in your arms, legs, neck, or back?
- Do you have any swelling of your joints?
- Do you have any difficulty washing and dressing?
- Do you have any difficulty going up or down stairs or steps?

Musculoskeletal conditions are often associated with systemic features, and general inquiry should be made about the person's health.

Screening examination

Any significant abnormalities of the spine, arms, or legs should be identified by inspection at rest and during certain movements and with brief palpation and stress tests of selected joints. Normality is looked for in the appearance, posture, and resting position of the joints and in smooth movement through the expected normal range. Whenever any joint is affected by a musculoskeletal condition, one movement is usually nearly always affected, and it is these movements that are assessed in this screening. For such screening to be part of the routine examination of all patients, it has to be quick, simple, and easy to annotate. This screening was developed to meet these criteria.¹ The gait, arms, legs, and spine (G, A, L, S) should be assessed.

- *Gait.* Observe the patient walking forward for a few feet, turning, and walking back again. Abnormalities in the different phases should be recognized: heel strike, stance phase, toe-off, and swing phase (Fig. 28.1). Look for abnormalities in movement of the arms, pelvis, hips, knees, ankles, and feet during these phases.
- *Inspection of the standing patient.* View the patient from the back, side, and front to look for any abnormalities, in particular, abnormalities in posture and symmetry. Examine for tenderness by applying pressure at the midpoint of each supraspinatus muscle and rolling an overlying skinfold.

Fig. 28.1 The main phases of the gait cycle are heel strike, stance, toe off, and swing. The phases relate to the shaded leg.

- **Spine.** Ask the patient to flex the neck laterally to each side. Place several fingers on the lumbar spinous processes, ask the patient to bend forward and attempt to touch the toes while standing with the legs fully extended, and observe and feel for normal movement.
- **Arms.** Ask the patient to place both hands behind the head with the elbows fully back. This is a sensitive test for many components of the shoulder apparatus. Straighten the arms down to the side of the body and then inspect with the patient's elbows bent to 90 degrees, palms down, and fingers straight. Turn hands over and make a tight fist with each hand. Place, in turn, the tip of each finger on the tip of the thumb. Squeeze the metacarpals from the second to the fifth.
- **Legs.** With the patient reclining on an examination table, flex each hip and knee in turn while holding and feeling the knee. Then passively rotate the hip internally. With the patient's leg extended and resting on the couch, examine for tenderness or swelling of the knee by pressing down on the patella while cupping it proximally. Squeeze all the metatarsals and finally inspect the soles of the feet for callosities.

Any abnormalities identified should be documented so that they can be assessed more completely.

ASSESSING A MUSCULOSKELETAL PROBLEM

General aims

When someone has or is identified at screening as having a musculoskeletal problem, the aim of consultation is to fully characterize the problem that the person is complaining of to identify the syndrome and then make a clinical diagnosis or at least offer a differential diagnosis. This next step needs basic knowledge of musculoskeletal conditions and may require investigations. Assessment of a person's musculoskeletal problem therefore requires not just good clinical skills but also knowledge of functional anatomy, the features of common musculoskeletal conditions, their differential diagnosis, the role of investigations, risk factors and complications, and their probable prognosis. Musculoskeletal conditions are common and can coexist. It should not be assumed that each symptom relates to a single diagnosis.

The impact of the musculoskeletal problem must be identified in terms of symptoms such as pain, physical disability, depression, and fatigue, as well as with respect to its effect on activities of daily living and how it affects the person's ability to participate in what that person wants and needs to do. In addition, interpersonal relationships with family, caregivers, and friends may be affected, and the person often expresses fear of the future.

The patient's concerns must also be identified if the consultation is to fulfill the expectations of the patient, as well as those of the physician (Table 28.1). They must have a full understanding of the treatment plan and what

TABLE 28.1

What is the expectation of the consultation?

Patient expectation	Clinician expectation
What is wrong?	Is any abnormality present?
What will happen? <i>Will I get better? Will I become worse and unable to do what I want and need to do?</i>	What is the abnormality? What is the cause? What effect is it having?
What can you do about it? <i>Can it be cured or just relieved?</i>	Are any predisposing or risk factors present?
What can I do about it? <i>Will a diet or complementary therapies help? Should I exercise?</i>	Have any complications occurred? What treatment is indicated? What has been the response to previous treatment?
Am I getting better?	Has the patient responded to current treatment? What is the prognosis?
If I am not improving, am I receiving the best treatment?	

expectations to have. If the condition is chronic, the patient must have the ability to actively participate in management of the condition, and for this the patient requires knowledge and support. It is important for the physician to show empathy and gain the confidence of the person to establish a relationship of trust and understanding.

If a person is being reassessed, response to treatment needs to be determined both in terms of the disease process and in terms of the impact that it has on the person. It must be compared with the expected response to determine whether any modification of the treatment plan is needed. Many standardized assessments for musculoskeletal conditions can be used to measure impact² and monitor response to treatment³; such assessments are considered within the relevant disease area elsewhere in this book.

The consultation to assess a musculoskeletal problem

The consultation consists of several phases: listening and observing, inquiring, performing an examination, ordering investigations, and making and communicating the conclusion. History taking is by far the most important part of the evaluative process, complemented by physical examination, to confirm the nature of the musculoskeletal problem. One should listen throughout the consultation to understand the patient's concerns, needs, and expectations. Observe the patient's overall appearance, movements, and manner. In the majority of cases it is necessary to make a complete assessment of the entire person, particularly since an apparently simple local problem may be the manifestation of a more generalized condition or the symptoms may be referred from a distant site. When dealing with a musculoskeletal problem, investigations are usually necessary only to confirm clinical suspicion regarding the diagnosis and to help gauge disease activity, prognosis, and choice of treatment. They should follow logically from the findings of the consultation and be performed only if the results will influence decision making.

Any consultation should close with a full discussion of the findings and conclusions so that the person understands the cause, the treatment, and its probable benefits and risks; what can be done by the person themselves, and the probable outcome. Such discussion needs to consider the patient's needs and expectations. Because many musculoskeletal conditions are chronic or recurrent, the patient will need a detailed explanation to enable active participation in care. Further support can be given by other health care professionals or be obtained from written material, the Internet, and patient support groups.

History

First clarify what has brought the patient to the consultation and what the patient's expectations are. Characterize the nature of the condition and its impact. Explore other potentially relevant factors such as the medical history, risk factors related to lifestyle or occupation, and factors that may influence its impact, such as the patient's expectations and socioeconomic environment (Box 28.1).

What are the symptoms?

Symptoms specifically related to musculoskeletal conditions are most often pain and stiffness, frequently accompanied by loss of function, which can

BOX 28.1 CHARACTERIZATION OF A MUSCULOSKELETAL PROBLEM

- What are the symptoms?
- Site and distribution of the symptoms
- Chronology
- Associated symptoms
- Preceding illnesses or injuries and other relevant clues
- Response to health interventions
- Its impact on activities, participation, and quality of life

BOX 28.2 SYMPTOMS OF A MUSCULOSKELETAL PROBLEM**Specific symptoms**

- Pain
- Stiffness
- Swelling
- Deformity
- Weakness
- Instability
- Loss of function

General symptoms

- Fatigue and malaise
- Emotional lability—fear, anxiety, depression
- Sleep disturbance
- Symptoms of systemic diseases

Red flags

- Weight loss
- Fever
- Temple headache/pain with scalp tenderness/visual disturbance
- Loss of sensation
- Loss of motor function
- Difficulties with urination or defecation

Other possible symptoms

- Color changes or coldness of digits or limbs
- Altered sensation

limit activities and restrict participation. Mobility and dexterity are most often limited. Nonspecific symptoms may be present as well. Red flags for potentially serious conditions must be recognized (Box 28.2).

Characterization of these symptoms helps the physician differentiate a musculoskeletal complaint into one of several "syndromes":

- Joint problem, including inflammatory and noninflammatory (osteoarthritis)
- Regional pain problem (including periarticular and soft tissue problems)
- Neck or back pain problem
- Generalized pain (and/or stiffness) problem
- Muscle problem (pain, stiffness, or weakness)
- Bone disorder
- Systemic problem with musculoskeletal symptoms

Pain

The characteristics of the pain can help identify its cause. Nociceptive pain results from a stimulus or lesion in peripheral tissues that causes a painful impulse to be transmitted by an intact nervous system, whereas neuropathic pain arises as a direct consequence of a lesion or disease affecting the nervous system. These types of pain need to be distinguished, and different causes of nociceptive pain have their own characteristics. Pain may also be referred from another site. Also identify the effect of pain on the person with respect to function and quality of life.

What is the site and distribution of the pain?

Ask the patient to demonstrate where the pain is felt and where it is most severe. Is the pain generalized or localized? How easily can it be localized? Articular and periarticular pain often radiates widely and presents far from its origin. Such referred pain is felt in the dermatome related to the myotomal or sclerotomal origin of the affected structure (Table 28.2). Pain from bone and periosteum radiates little and is localized more reliably.

TABLE 28.2**Common patterns of referred pain**

Source of pain	Pattern of referral
Cervical spine	Occiput, shoulders
Shoulder	Lateral aspect of the arm
Lateral epicondyle	Midforearm region
Carpal tunnel	Radial fingers, occasionally the forearm or arm
Lumbar spine	Sacroiliac joints, buttocks, posterior aspect of the thigh, lower part of the leg, foot
Hip joint	Groin, medial aspect of the thigh, medial aspect of the knee, greater trochanter, buttock above the gluteal fold
Trochanteric bursa	Lateral aspect of the thigh, buttock

TABLE 28.3**Patterns of pain**

Type	Pain pattern	Cause
Bone pain	Pain at rest and at night	Tumor, Paget disease, fracture
Mechanical joint pain	Pain related to joint use only	Unstable joint
Osteoarthritic joint pain	Pain on joint use, stiffness after inactivity, pain at the end of the day after use	Osteoarthritis
Inflammatory joint pain	Pain and stiffness in the joints in the morning, at rest, and with use. Acuteness and severity can indicate the probable cause	Inflammatory, infective, crystal induced (acute, exquisite tenderness)
Periarticular and soft tissue pain	Pain on selective movements, localized periarticular or soft tissue tenderness	Bursitis, tenosynovitis, tendinitis, enthesitis
Neuropathic	Diffuse pain and paresthesia in the dermatome worsened by specific activity	Root or peripheral nerve compression
Referred	Pain unaffected by local movement	

Widespread pain can be due to fibromyalgia or polymyalgia rheumatica, whereas pain in several joints suggests an arthropathy. Myeloma or metastatic malignancy must be considered in those with multiple sites of pain that are related not just to joints. Examination of the patient is necessary to clarify the anatomic site of origin of the pain.

What are its characteristics and pattern?

The features of the pain, the time and mode of onset, and its diurnal pattern provide diagnostic clues. Severity is subjective and is not diagnostic alone, although its perceived severity indicates the probable impact that it is having. Certain musculoskeletal conditions are characterized by specific patterns of pain (Table 28.3). For example, gout usually begins in the middle of the night with a pricking sensation in the great toe and quickly escalates into an intolerable persistent burning pain, whereas osteoarthritis is characterized by use-related pain and stiffness of the affected joints with inactivity. Mechanical pain is generally related to use. Inflammatory joint pain is present at rest and with use and is usually worse at either end of the day. Neuropathic pain is diffuse and described as superficial burning, stinging, or pricking pain; as deep aching pain; or as paroxysmal, electric shock-like pain. It is often evoked by a specific activity such as skin stimulation, pressure over affected nerves, and changes in temperature or emotion and is associated with paresthesia in the dermatome. It may include allodynia (pain caused by a stimulus that does not normally provoke pain), hyperalgesia (when there is an increased sensitivity to pain), and hyperesthesia (when a non-noxious stimulus causes the sensation of pain). Bone pain is typically present at rest and at night. These types of pain give clues but are not diagnostic.

The pattern of evolution of the pain should be established in conjunction with the development of any other symptoms—how the patient has arrived at the present situation.

What precipitates, worsens, or improves the pain?

Periarticular problems are often induced by a specific type of repetitive activity. Spinal stenosis can be suspected from a history of activity-related buttock and leg pain that improves rapidly with rest only to recur after further activity, and walking downhill (which extends the spine) causes more pain than walking uphill or cycling. The response to exercise in contrast to rest is a typical feature of sacroiliitis or spondylitis. Rest usually improves the pain from osteoarthritis but has little effect on inflammatory pain. The response to antiinflammatory analgesics versus simple analgesics can help distinguish an inflammatory cause of the symptoms, such as ankylosing spondylitis, from mechanical back pain; the response of polymyalgia rheumatica to glucocorticosteroid therapy is characteristic.

What is its effect on the person?

Pain is a subjective sensation that cannot be felt by others. It can be measured with a visual analog scale, but the degree to which it disrupts the person's life in terms of activities and participation that the person needs and wants to do gives a more meaningful indication of its severity and impact. Pain frequently disturbs sleep, which magnifies its impact.

Stiffness

People often describe a generalized “stiffness” after prolonged rest or the day after an unusual level of exercise, which is more common as people age. More specifically, people frequently describe stiffness related to symptomatic joints. An inflammatory joint disorder is generally associated with prolonged morning and evening joint stiffness, whereas osteoarthritis is associated with short-lived stiffness after inactivity. Morning stiffness of the girdle muscles is characteristic of polymyalgia rheumatica, which can be so severe that it is virtually impossible to roll out of bed and dress, although a few hours after getting up the patient may be virtually asymptomatic. The duration of morning stiffness can indicate the activity of rheumatoid arthritis or polymyalgia rheumatica.

Stiffness of movement of the fingers can relate to tenosynovitis (sometimes with triggering), joint disease, or tightening of the soft tissues, such as with systemic sclerosis or Dupuytren contracture. “Stiffness” can also be used to describe a reduced or limited range of movement or by the patient to describe the difficulty in movement associated with muscle diseases such as inflammatory myositis, Parkinson disease, and motor neuron disease. A careful examination is necessary to be certain about correct attribution of this symptom.

“Locking” describes the sudden inability to perform a particular movement and suggests a specific mechanical event in which some internal derangement actually causes the joint to lock in one position until a trick movement or help is used to free it. This is a classic symptom of a loose body or torn meniscus of the knee joint, but it also occurs in the finger with triggering secondary to stenosing tenosynovitis.

Swelling and deformity

Swelling may involve soft tissues, the joint, or bone. Did it follow an injury? Did it appear rapidly or slowly? Is it painful? Does it come and go, or is it gradually enlarging? Any swelling needs careful examination to establish its nature and cause. Joint swelling is a sign of disease, and examination is necessary to confirm whether it is related to the joint or a periarticular structure and to establish whether it is due to an effusion, synovial proliferation, or bony growth. Imaging such as ultrasound may be required. Recognition of any deformity requires familiarity with the musculoskeletal system to distinguish normal variation from abnormal findings.

Weakness and instability

Weakness can indicate a muscle disorder such as inflammatory myositis or a neuropathy. The pattern of muscle weakness, whether generalized or in a central or peripheral distribution, should be established. Regional weakness is more likely to have a specific cause. However, “weakness” may be used by a patient to describe different things, such as general fatigue, difficulty with movement because of joint disease or pain, or regional weakness of a joint or limb caused by the local muscle wasting that can accompany joint damage. A sensation of “giving way” and general instability of the lower limbs can result from knee pain or weak quadriceps muscles. A joint may be unstable and suddenly give way because of muscle weakness, or it may be related to the ligaments being ruptured or lax in hypermobility. Examination is needed to characterize what is being described.

Loss of movement or function

Musculoskeletal conditions often cause difficulty performing various activities, which may be the main complaint. Establish whether any particular movements and functions are restricted and whether such restriction relates to pain and stiffness or is a primary problem. Painless loss of movement suggests tendon rupture or a neurologic cause.

Fatigue and malaise

Fatigue is a manifestation of most generalized rheumatic disorders, including rheumatoid arthritis, systemic lupus erythematosus (SLE), and most notably, fibromyalgia. Fatigue is sometimes related to depression. It may also be the consequence of poor sleep, which is often related to pain. Fatigue may be severely disabling and is very distressing to the person. The fatigue associated with rheumatoid arthritis or SLE is a good indicator of systemic disease activity.

People with inflammatory arthritis are often able to function well for several hours but then suffer overwhelming fatigue. The fatigue of fibromyalgia is usually associated with lack of concentration and poor-quality sleep. Polymyalgia rheumatica is frequently accompanied by a feeling of sudden aging, with rejuvenation occurring rapidly after a moderate dose of corticosteroid.

Emotional lability

Fear and anxiety are common accompaniments of a musculoskeletal problem and are influenced by factors such as knowledge of the possible diagnosis, expectations for prognosis, future aspirations, and fear of losing independence. Emotional lability, depression, and other psychiatric disturbances can also be the direct result of a rheumatic disease such as SLE. In addition, sleep disturbance secondary to pain can affect mood.

What is the pattern and chronology of the symptoms?

The distribution and chronologic pattern of each symptom need to be established. How did the patient arrive at the present situation? When and how did it start—was the onset sudden or gradual, spontaneous, or after some specific event such as trauma or an infection? What was the subsequent course with respect to time and the pattern of distribution of the symptoms? If articular, does it involve peripheral small joints or large joints or have an axial distribution? Has it followed an additive, intermittent, or flitting course? Is it symmetric or asymmetric? What associated symptoms or signs have developed and when? Do the symptoms fit some recognized pattern? It is important, however, to avoid forcing the symptoms into a pattern—musculoskeletal conditions are common, and different conditions can coexist.

The pattern is important in identifying the possible cause. For example, a traumatic condition obviously relates to a specific event, whereas a degenerative pathology is usually manifested in a slow, insidious fashion. Crystal-related inflammation is particularly rapid in onset and severe, but self-limited, whereas untreated sepsis causes a steadily worsening situation over a few days. Many of the idiopathic inflammatory or immune-mediated rheumatic diseases have a variable course with spontaneous remissions and exacerbations, whereas others, such as reactive arthritis, follow a more predictable course with the sequential development of mucocutaneous and joint inflammation over a period of a few weeks after the initiating event, which gradually subsides over months. Other specific patterns include palindromic rheumatism, which as the word implies, involves episodes of arthritis affecting one or two joints that come and go spontaneously over a few days.

Associated symptoms, preceding factors, red flags, and other clues

Musculoskeletal conditions often have systemic features, and systemic disorders often have musculoskeletal symptoms. It is therefore important to ask about the patient's general health and inquire about the presence of systemic symptoms, such as fever, night sweats, or weight loss and other “red flags” (see [Box 28.2](#)), which may indicate the presence of a serious systemic disorder such as a malignancy, infection, or active inflammatory disease. Review the patient's general health—current, recent, and past. Questions should be directed by knowledge of associated symptoms of the conditions under consideration ([Table 28.4](#)). For example, one should inquire about a recent diarrheal illness, urethritis, or psoriasis and mucocutaneous problems with the seronegative spondyloarthritides. Did any preceding trauma or repetitive or unusual use take place? The previous medical history may include past events that give clues to the present problem, such as a previous attack of unexplained epilepsy in someone with SLE or fetal loss or thrombosis with antiphospholipid syndrome. In other cases, relevant

TABLE 28.4
Associated symptoms, signs, and conditions

	Symptom	Possible diagnosis
Neurologic	Headaches	SLE, temporal arteritis
	Numbness or paresthesia	Neuropathy—compression
	Weakness	Myositis, neuropathy
	Stroke	Antiphospholipid syndrome
	Epilepsy	SLE
Mouth	Dry mouth	Sjögren syndrome
	Mouth ulcers	Reactive arthritis, Behçet disease, inflammatory bowel disease
Eyes	Dry eyes	Sjögren syndrome
	Red eyes	Spondyloarthritis
	Visual loss	Temporal arteritis
Skin	Rash	
	Psoriasis	Psoriatic arthritis
	Livedo reticularis	SLE
	Erythema nodosum	Acute sarcoid or erythema nodosum arthropathy
	Telangiectasia	Systemic sclerosis
	Other	Viral—rubella, human parvovirus
	Photosensitivity	Connective tissue disease
	Ulcers	Behçet disease, vasculitis
	Raynaud phenomenon	Connective tissue disease
	Nodules	Osteoarthritis, rheumatoid arthritis, gout, hyperlipidemia, SLE, rheumatic fever, polyarteritis nodosa, multicentric histiocytosis
	Alopecia	SLE
Respiratory	Pleuritis	Connective tissue disease
	Breathlessness	Pulmonary involvement with inflammatory disease, e.g., systemic sclerosis, rheumatoid arthritis
Gastrointestinal	Indigestion, history of peptic ulcer	Nonsteroidal-associated gastritis or ulceration
	Diarrheal illness	Reactive arthritis, inflammatory bowel disease
Genitourinary	Renal stones	Gout
	Dysuria	Reactive arthritis, Behçet disease, acute gonococcal arthritis
	Genital ulcers	Reactive arthritis, Behçet disease, acute gonococcal arthritis
	Vaginal discharge	Reactive arthritis, Behçet disease, acute gonococcal arthritis
Trauma	Fracture	Osteoporosis
	Ligament rupture	Osteoarthritis in the future
	Sprains and strains	Hypermobility syndrome
Nonspecific symptoms	Malaise	Inflammatory disease, malignancy
	Fever	SLE, septic arthritis
	Weight loss	Inflammatory disease, malignancy
	Fatigue	Inflammatory disease
	Anorexia	Inflammatory disease, malignancy
Hematologic	Aging	Polymyalgia rheumatica
	Thrombosis/thromboembolism	Antiphospholipid syndrome
Obstetric history	Anemia	Inflammatory disease
	Fetal loss—early and late	Antiphospholipid syndrome
	Intrauterine growth retardation	Antiphospholipid syndrome
	Preeclampsia	Antiphospholipid syndrome

SLE, systemic lupus erythematosus.

previous medical events may relate to the associations between disorders, such as hypermobility in childhood or past joint trauma as risk factors for osteoarthritis.

The family history can help in the differential diagnosis in some situations, although almost everyone has a relative with arthritis and familial associations are seldom predictive. Importantly, a family history gives personal experience of the potential impact of a rheumatic condition and affects the person's anxieties about the diagnosis and prognosis. Useful clues include a recent flulike illness in the family or other close contacts, which raises the possibility of a viral arthritis; nodal arthritis affecting the mother when deciding whether small-joint polyarthralgia of the hands is early rheumatoid arthritis or nodal osteoarthritis; or a family history of ankylosing spondylitis, iritis, or psoriasis in a young man with back pain.

Recognized risk factors for the development and outcome of musculoskeletal conditions include obesity, lack of physical activity, poor diet, smoking, and excess alcohol intake, as well as activities that expose people to sprains and strains, such as sports or occupation. Recognized “yellow flags” for chronicity of back pain include job dissatisfaction, unavailability

of light work, depression, and low educational level. All this information may need to be considered when fully evaluating someone's musculoskeletal condition.

Previous health interventions and symptom response

Previous and present management should be reviewed. What has the patient been told and what knowledge and understanding does the patient have? What interventions have been tried—prescription and over-the-counter pharmacologic treatments, physiotherapy, supplements, or complementary therapies? What was the response to them? Did the patient benefit or sustain any adverse effects? What is the patient's attitude to and probable compliance with any treatment?

The response to treatment can be of great relevance in understanding the nature of the problem, such as the response of many inflammatory disorders such as ankylosing spondylitis to antiinflammatory therapy or the rapid and almost miraculous response to corticosteroids that is typical of polymyalgia rheumatica. Drugs themselves may also be the cause of the problem, as in drug-induced lupus and thiazide diuretics in gout.

Fig. 28.2 World Health Organization's International Classification of Functioning, Disability, and Health model of disability. (Adapted from World Health Organization. *International classification of functioning and health*. Geneva: WHO; 2001.)

What is its impact?

The impact of the musculoskeletal condition must be assessed in relation to the patient's needs and aspirations. The framework of the World Health Organization's International Classification of Functioning, Disability, and Health⁴ (Fig. 28.2) provides a useful way to look at the effect of any health condition on the functioning of an individual in terms of loss of function, limitation of activities, and restriction of participation within the personal and environmental context of the person's life.

Explore what the patient needs to do and would like to do in everyday activities, including personal care; the home environment; tasks for others, whether paid or unpaid; and personal, social, and leisure activities. Musculoskeletal problems often affect mobility and dexterity. Pain disturbs sleep. What is difficult, requires assistance, or has become impossible to do? Talk a patient through a typical day and also remember to ask about any problems participating in work or leisure activities, as well as personal activities such as toileting or sexual activity. Find out the patient's frustrations and concerns.

Learn whether and how the patient has coped with the limitations. Establish the amount of physical and emotional support that the patient has from family, friends, other caregivers, or social services. Does this support meet the patient's needs? How has the condition affected the patient's economic situation? Helping the patient problem-solve is an important part of the management plan.

The effect on health-related quality of life can be formally assessed by using various validated generic and disease-specific questionnaires such as the Health Assessment Questionnaire.²

Social history and occupation

Knowing the patient's social history is important in assessing the condition and its impact and in planning management. The personal and environmental context plays an important role in the impact. Occupation is also important because it may have a causal role or an effect on the symptoms, or alternatively, the symptoms may have an effect on occupation. Understanding the person's occupation can also give a clearer idea of the person's needs and how to help the person return to the occupation.

Examination

A careful examination is necessary to confirm clinical suspicions gained from the history. It also complements a screening assessment by characterizing any abnormality of the musculoskeletal system that has been identified. Examination of the musculoskeletal system is principally an exercise in applied anatomy. Is the pain originating from the bone, muscle, joint, or periarticular structures? Is the joint pain inflammatory or mechanical in origin? Is the origin of the pain local with tenderness or pain on movement, or is it referred? How painful is it to touch or move, and is this consistent with the history? The examination may focus on the symptomatic structures, but it is usually most informative to do this as part of a general examination of the musculoskeletal system and the entire patient.

Aims of examination

The aim of examination of the musculoskeletal system is to answer four questions:

1. Are the findings normal?
2. What is the abnormality?

Fig. 28.3 Testing for warmth by using the back of one's hand.

Fig. 28.4 Redness as seen in gout. This is a valuable indicator of the intensity of underlying joint inflammation.

3. What is the pattern of distribution?
4. What other features are of diagnostic importance?

These, in combination with the history, should establish the differential diagnosis.

Are the findings normal?

The expected appearance and ranges of movement of the musculoskeletal system need to be recognized. Abnormalities observed may be an abnormal resting position, swelling, deformity, muscle wasting, or abnormal movement. Warmth, crepitus, tenderness on palpation, instability, or weakness may be present.

What is the abnormality?

The nature of the abnormality needs to be established. What structures are involved? What are the characteristics of the abnormality? Is evidence of inflammation, damage, deformity, or biomechanical abnormalities present? These abnormalities are not mutually exclusive; a combination of them may be found.

Inflammation. An inflamed joint is characterized by pain, tenderness, warmth, redness, and swelling. Pain is often apparent by observing movement, and tenderness is elicited by gentle palpation. Warmth is detectable mainly in medium-sized and large joints, for example, the knee, ankle, and wrist joints (Fig. 28.3). Redness is uncommon but is seen with gout, especially around the big toe (Fig. 28.4), and with sepsis. Swelling of an inflamed joint is characterized by its articular origin, is fluctuant because of synovial proliferation or effusion, and is tender, whereas in osteoarthritis, bony swelling along the joint line may be apparent. A number of specific techniques can be used for detection of synovitis and effusion at different joints (Fig. 28.5). One must identify the inflamed structure. Inflammation of periarticular structures such as bursae or entheses must be carefully distinguished from inflammation of the joint. Inflammation of muscle is characterized by tenderness.

Damage. Joint damage is recognized by the presence of deformity, crepitus, movement in an abnormal plane, and loss of joint range of movement not secondary to pain and in the absence of features of current inflammation. Crepitus is an audible and palpable sensation resulting from the movement of one roughened surface over another. In osteoarthritis, the crepitus has a fine quality. This should be distinguished from the coarser, clicking sensation encountered in normal joints.

Deformity. Joint deformity usually refers to malalignment or subluxation of two articulating bones in relation to one another and is identified by abnormal posture, often more apparent on weight bearing or with certain movements, such as occurs with developmental scoliosis of the spine. A severely damaged joint from rheumatoid arthritis or osteoarthritis may cause

movement in an abnormal plane. For example, the elbow is a simple hinge joint; hence its normal range is flexion/extension only, and any other movement, such as elbow abduction, is abnormal and likely to indicate gross joint disruption. Paget disease may be accompanied by bone deformity.

Biomechanical abnormalities. Every joint has a normal posture and spectrum of normal range of joint motion, which varies with age, gender, genetics, and ethnic origin. Motion outside this range may be considered hypermobility or hypomobility. Biomechanical abnormalities can result in symptoms such as scoliosis and back pain, joint hypermobility syndrome is associated with joint pain, and foot pain is often caused by abnormal biomechanics. Joint range is reduced by joint inflammation (the bulk of the inflamed synovium and the effusion) or by irreversible damage to the joint structures (articular cartilage and subchondral bone). Movement is first lost from the extremes of the range. Complete loss of movement is described as ankylosis.

What is the pattern of distribution?

The distribution of involvement of the musculoskeletal structures is important in the diagnosis of musculoskeletal conditions because certain patterns are characteristic (Table 28.5 and see Chapter 29). Several different problems may affect an individual; the apparent pattern may be a false clue to the diagnosis. Examination is needed to confirm the pattern of distribution and to establish whether the various problems relate to a single diagnosis or to several coincident problems, such as the coexistence of nodal osteoarthritis and rheumatoid arthritis.

Fig. 28.5 Testing for swelling. (a) The bulge sign in the knee. The back of the hand gently pushes the fluid from one side of the knee to the other to fill out the "dimples" on either side of the patella. This is most helpful in detecting small knee effusions. (b) The patellar tap. One hand is used to cup the patella and compress the suprapatellar pouch, and the fingers of the other hand press down on the patella to feel for cross-fluctuation. (c and d) Swelling/fluctuation of the small joints of the hand. Detect cross-fluctuation at the joint line with the index fingers and thumbs by squeezing and feeling each side of the joint (as illustrated) or by squeezing and feeling from side to side with one index finger/thumb and squeezing and feeling from the palmar to the dorsal aspect with the other index finger/thumb ("interlocking C").

What other features are of diagnostic importance?

Some systemic features (see Table 28.4) may be of diagnostic importance or of value in assessing severity. Many of these features are easily visible skin signs such as psoriasis, nail fold capillary abnormalities, or telangiectasia, whereas others, such as pulmonary fibrosis or neuropathy, will need to be identified by careful general examination.

Method of examination

One should look at the entire person, including posture and movement, and each region is then examined by comparing one side with the other. It is usually necessary to examine the full musculoskeletal system to correctly assess the problem, but most emphasis is placed on the probable origins of the symptoms while remembering that pain is frequently referred and that any examination must consider all possible causes. Explain to the patient what you are about to do and ask whether the patient thinks that any part of the examination is likely to be painful.

The key elements of the examination to identify the clinical signs of musculoskeletal conditions (Box 28.3) are to look, feel, move, and stress (Table 28.6). These steps are usually performed in an integrated manner. Special tests may be necessary to identify specific problems.

Look

Attitude and spontaneous movement. Observe the person when sitting and undertaking various functional movements during the consultation for any abnormalities associated with musculoskeletal conditions. An inflamed joint is most comfortable when the periarticular structures are at greatest laxity and intracapsular pressure is least. Pain is most severe when intracapsular pressure is greatest. An indication of the severity of the pain is given by the protection with which the person treats the affected region. Is ease of movement in keeping with the severity of pain described?

Swelling and deformities. Look for swelling, but palpate to characterize whether it is due to synovial thickening, joint effusion, bony enlargement, or a combination of these features. Ultrasound is often used to better characterize swelling. Look for any deformities of the joints, bones, or spine. A number of terms are in common use to describe deformities:

- **Kyphosis:** forward curvature of the thoracic spine
- **Scoliosis:** lateral curvature of the spine
- **Dislocation:** articulating surfaces displaced so that they are no longer in contact with one another

BOX 28.3 CLINICAL SIGNS OF MUSCULOSKELETAL CONDITIONS

- Attitude
- Deformity
- Swelling
- Skin changes
- Muscle wasting
- Tenderness
- Restricted movement
- Crepitus
- Warmth
- Muscle weakness
- Instability
- Limited function

TABLE 28.5

Characteristic patterns of involvement of the musculoskeletal system

Diagnosis	Symmetry	No. of joints involved*	Large or small	Distribution	Upper or lower limbs
Rheumatoid arthritis	Symmetric	Polyarthritis	Large/small	Peripheral	Upper/lower
Ankylosing spondylitis	Asymmetric	Oligoarthritis	Large	Central and peripheral	Lower
Psoriatic arthritis	Asymmetric	Oligo/polyarthritis	Large/small	Peripheral	Upper/lower
Reactive arthritis	Asymmetric	Oligo/polyarthritis	Large/dactylitis	Peripheral	Lower
Gout	Asymmetric	Mono/oligoarthritis	Large/small	Peripheral	Lower/upper

*With oligoarthritis, five or fewer joints are affected; with polyarthritis more than five joints are affected.

- **Subluxation:** partial dislocation
- **Fixed flexion:** loss of extension so that the joint is permanently flexed
- **Valgus:** a lower limb deformity in which the distal part is directed away from the midline (e.g., hallux valgus)
- **Varus:** a lower limb deformity in which the distal part is directed toward the midline (e.g., genu varum).

Examination is necessary to determine whether these deformities are correctable. Commonly encountered specific deformities of the hand are shown in Figure 28.6.

Skin. Look at the skin, both that overlying the affected region for redness indicating marked inflammation and for other skin changes, including

psoriasis, ulceration, livedo reticularis, and nodules such as tophi, erythema nodosum, and rheumatoid nodules (Table 28.7). Look carefully at the hands and nails because of the many abnormalities that can occur.

Wasting. Look for loss of muscle bulk. Arthropathy can cause widespread wasting around the joint. More localized wasting suggests a tendon, muscle, or peripheral nerve lesion. Swelling of a joint can give a false impression of adjacent loss of muscle.

TABLE 28.8

Possible causes of tenderness

Site	Possible cause
Muscular: localized	Myofascial lesion
Muscular: generalized	Fibromyalgia, myositis
Joint line: generalized	Arthropathy, capsular disease
Joint line: localized	Abnormality of intracapsular structure, e.g., medial knee joint line tenderness with a meniscal tear
Periarticular	Bursitis, enthesopathy, sarcoid
Bone	Bone pathology: osteoporotic fracture or invasive lesion
Vertebral	Bone pathology: osteoporotic fracture or invasive lesion

Feel

Warmth. First feel gently for warmth, which is best evaluated by using the backs of the fingers and comparing the finding with that of a normal structure (see Fig. 28.3). Warmth is a cardinal sign of inflammation but may be detected only over large joints.

Tenderness. The presence and localization of tenderness are important in identifying the cause of the problem (Table 28.8). Examine carefully to establish whether it is the joint line or periarticular region. Is the tenderness muscular, either generalized, such as in myositis, or localized, such as the characteristic tender spots of fibromyalgia? Does it involve the temporal artery or temporomandibular joint? Is tenderness absent despite pain? Feel for tenderness by gradually increasing pressure while watching the person for any reaction and releasing as soon as the presence of tenderness is established. Apply pressure only until blanching of the nail of the examining fingers occurs. Percuss the vertebrae to detect localized tenderness.

Swelling. Determine the precise location and anatomic associations of the swelling, whether it is tender, and whether it involves fluid, soft tissue, or bone. Different types of swelling have typical characteristics. Swelling of a joint is confined by the capsule and is most apparent with any weaknesses in the capsule; for example, an effusion in the knee may be associated with a popliteal cyst. Fluid and soft tissue are ballotable; this is the principle of the patellar tap and the interlocking-C examination of the interphalangeal joints (see Fig. 28.5).

Movement. Palpating the joint and periarticular structures while moving gives further information about the pain and tenderness, as well as crepitus from the joint or tendon sheaths.

Move

Three methods can be used to assess joint movement—active, passive, and against resistance.

- To examine joints, a combination of active and passive movement is recommended.
- To detect lesions in tendons or at tendon-osseous junctions, the against-resistance method is principally of use.
- To measure muscle power, the against-resistance method is the principal technique.

First establish the active range, and if reduced, see whether it is greater with passive movement, but be cautious because this may be painful. Familiarity with the normal ranges and planes of movement of the joints is needed. If the problem is unilateral, compare the affected with the unaffected side. Formal measurement of range of motion is of limited value. Involvement of the joint, in particular, synovitis, usually restricts all movement. Restriction of movement in one plane is characteristic of periarticular lesions, tenosynovitis, or internal derangement of the joint. Pain in all directions of movement is associated with synovitis. Pain in just one plane of movement indicates a localized articular or periarticular problem. Pain throughout the range of movement is more characteristic of mechanical problems such as osteoarthritis.

Resisted active movement is valuable in identifying problems related to the muscle tendon or enthesis. This should be performed with the joint in neutral position. Reproduction of pain indicates that it is originating from the muscle, tendon, or tendon insertion related to that movement. Passively stretching the tendon or ligament may also reproduce the pain.

BOX 28.4 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM**Gait**

- Observe the patient walking forward for a few feet, turning, and walking back again.

Posture

- Observe the patient from the back, side, and front to look for any abnormalities, in particular, abnormalities in posture and symmetry.

Listening during joint movement may detect fine crepitus secondary to cartilage damage, crackling associated with hypermobility, or clonking caused by a loose body or irregular surfaces such as severe damage. Audible tendon friction rubs may be heard in patients with systemic sclerosis.

Stress

Joint stability should be assessed by stressing a joint. Stability may be abnormal because of generalized hypermobility, ligament rupture subsequent to trauma or inflammation, capsular inflammation, or loss of articular cartilage and changes in bone as a result of osteoarthritis or rheumatoid arthritis.

Special tests

Various special tests are used for specific diagnoses that are not within the scope of this overview but are considered elsewhere in this text (see Chapters 71-82, as appropriate).

General examination

A full general examination forms an important part of the assessment of a person with a musculoskeletal problem. More frequent problems relate to the skin and nails, neurologic system, and eyes (see Tables 28.4 and 28.8).

Regional examination of the musculoskeletal system

A systematic approach to examination should be taken, but be sure to address any questions raised by the history or screening examination. The sequence can vary, but in general it is easiest to look at the patient as a whole and during walking and standing to observe gait and posture. Then work from the head downward, first with the patient standing to examine the upper limbs, spine, and pelvis and then supine to complete the examination of the pelvis and spine and to examine the lower limbs by comparing one side with the other (Boxes 28.4 through 28.7).

Gait

Gait demonstrates the integrated function of the lower limbs and will reveal abnormalities in the musculoskeletal system (see Fig. 28.1). Further assessment of the lower limbs will be necessary to identify the specific cause of any abnormality in gait.

Certain abnormal patterns of gait are well recognized. Pain in one limb causes avoidance of weight bearing by that limb and shortening of that phase of the gait cycle. The cycle is asymmetric, with shorter steps on the painful limb, and is described as an antalgic gait. Weakness of the hip adductors results in dipping of the pelvis to the other side when bearing weight on the affected limb. During the gait cycle the person leans the upper part of the body over the weak hip to compensate for this and maintain balance. This Trendelenburg gait is apparent as side-to-side movement of the shoulders when walking. Such movement of the shoulders is also seen with an inequality in leg length, which leads to tilting of the pelvis during the gait cycle. An alternative gait with leg length inequality is to flex the knee of the longer leg to clear the ground during the swing phase, with consequent dipping of the person up and down. A dropfoot results in a high-stepping gait to avoid tripping on the toes during the swing phase.

Posture

The normal symmetry of the body helps identify abnormalities in posture. Observe the whole person while standing and dressed only in underwear, and look for equality of height of landmarks—the tips of the shoulders, the scapulae, the pelvic brim, and the crease of the buttocks. Inspect the spine carefully for its normal curves and identify any scoliosis. Look at the feet during normal posture.

Documentation

The history and examination need to be documented. The history should form a clear story that another clinician can read, assess, and interpret. The

Text continued on p. 223

BOX 28.5 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM—HEAD, SPINE, AND PELVIS**Cervical spine**

- Look** Look for hyperextension caused by thoracic kyphosis or loss of normal lordosis.
- Feel** Percuss the vertebrae for tenderness.
Palpate the paraspinal muscles for spasm or tenderness.
- Move** Actively turn the head to the right, left, flexion, extension, rotation to the left and right, and lateral flexion to the left and right with the examiner gently guiding the head to ensure that maximum range is reached.
- Tests** Problems related to the cervical spine are often associated with neurologic symptoms and signs, which should be elicited.

Posture and alignment of the head and neck.

Extension.

Flexion.

Right rotation.

Left rotation.

Right lateral flexion.

Left lateral flexion.

**Temporomandibular joints**

- Feel** Palpate over the joint line for tenderness, crepitus, or clicking. The joint can be palpated anterior to the tragus or from within the external auditory meatus. Feel for crepitus or clicking on movement.
- Move** Open the mouth wide. Deviate the lower jaw side to side.

Mouth opening.

Mouth opening.

Side-to-side movement of the jaw.

Side-to-side movement of the jaw.

**Dorsal spine**

- Look** Look for any kyphosis or scoliosis. Look for any asymmetry of the scapulae.
- Feel** Percuss the vertebrae for tenderness.
Palpate the paraspinal muscles for spasm or tenderness.
- Move** Fix the pelvis by sitting and rotate the upper part of the body to the right and left with the examiner gently guiding the shoulders to ensure that maximum range is reached.

Right rotation.

Left rotation.

Look	Look for a normal lordosis or any scoliosis. Look for any asymmetry of the pelvic brim or the crease of the buttocks.
Feel	Percuss the vertebrae for tenderness. Palpate the paraspinal muscles for spasm or tenderness.
Move	While standing in an erect posture, bend forward as though trying to touch the toes, bend backward to arch the back, and bend from side to side. The person may be able to place the hands flat on the ground if hypermobile. Flexion can be more formally assessed with the Schober test by measuring extension of a line drawn when upright between 10 cm above and 5 cm below the level of the posterior iliac spines as identified by the dimples of Venus.
Stress	Tests for tension of the lumbar roots should be performed when patient is lying down. <i>Femoral nerve stretch test:</i> With the person lying prone, hold the ankle and passively flex the knee as far as it will go. The test is positive if pain is felt in the isolateral anterior aspect of the thigh. <i>Sciatic nerve stretch test:</i> With the person lying supine, gently raise the straight leg to the maximum angle achievable without significant pain and then dorsiflex the ankle. An increase in pain indicates sciatic nerve root tension.
Tests	The lumbar spine houses the lumbar spinal nerve roots, and neurologic symptoms and signs should be elicited.

Lumbar flexion.

Lumbar extension.

Left lateral flexion.

Right lateral flexion.

**Pelvis and sacroiliac joints**

Look	Look for asymmetry of the pelvic brim and the lower part of buttocks.
Feel	Palpate for tenderness in the buttocks. Palpate the sacroiliac joints for tenderness.
Stress	Stress the sacroiliac joints for tenderness. Various methods can be used to compress or distract the joint to elicit tenderness, such as pushing on both iliac wings when the person is lying supine.

Test for cruralgia.

Test for sciatica.

Test for sciatica.

BOX 28.6 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM—UPPER EXTREMITY**Shoulder**

- Look** Look for any asymmetry in the scapulae and posture or muscle wasting.
- Feel** Palpate over the midpoint of each trapezius and the supraspinatus to identify tender spots. Palpate over the acromioclavicular joint line, glenohumeral joint line, and bicipital groove.
- Move** Actively elevate the arms into the air.
Actively place the hands behind the head.
Actively place the hands behind the back.
Steady the scapula and, with the elbow at 90 degrees, rotate internally and externally; then passively abduct, flex, and internally and externally rotate the shoulder.
- Tests** Several methods can be used to establish whether impingement is present.

Abduction and external rotation.

Adduction, extension, and internal rotation.

External rotation.

Internal rotation.

Flexion.

Elevation.

Extension.

Abduction.

Adduction.

**Elbow**

- Look** Look for any swelling or deformity. Joint swelling is first apparent in the para-olecranon groove. The olecranon is a common site for bursitis and rheumatoid nodules.
- Feel** Palpate over the para-olecranon groove for synovial swelling or tenderness. Palpate over the medial and lateral epicondyles for tenderness. Assess the laxity of the skin if considering hypermobility.
- Move** Passively extend and flex the elbow and look for hyperextension.

Palpate over the medial and lateral epicondyles for tenderness.

Elbow flexion.

Elbow extension.

Assess for elbow hyperextensibility.

**Wrist**

- Look** Look for any swelling or deformity.
Swelling over the dorsum involves the joint or extensor tendon sheath. With active extension of the fingers, swelling of the extensor tendon sheath moves—the tuck sign.
Look for squaring of the base of the palm because of swelling of the carpometacarpal joint seen in osteoarthritis. Typical deformities in established rheumatoid arthritis are volar subluxation and radial deviation at the wrist with dorsal subluxation of the ulnar styloid.
- Feel** Palpate over the joint line for tenderness or synovial swelling.
- Move** Passively flex and extend the wrist.
Assess for hypermobility by passively moving the thumb toward the volar aspect of the forearm with the wrist in full flexion.
Use resisted flexion, extension, or pronation if assessing epicondylitis at the elbow.
- Stress** Assess stability of the inferior radioulnar joint by demonstrating movement when pressing down on the radial head—the piano key sign.

BOX 28.6 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM—UPPER EXTREMITY—cont'd

Wrist flexion.

Wrist extension.

Resisted active wrist extension to test for lateral epicondylitis.

Resisted active wrist flexion to test for medial epicondylitis.

Wrist ulnar movement.

Wrist radial movement.

Assess supination.

Assess pronation.

**Hand****Look**

Look for any swelling or deformity. Is the swelling specific to joints or tendons or is it diffuse?

Look for any associated clues. Much can be learned from the hand. Look for wasting of the small muscles; inspect the skin, nails, and nail beds.

Typical deformities in established rheumatoid arthritis are ulnar deviation of the fingers at the metacarpophalangeal joints, hyperextension at the proximal interphalangeal joint with flexion at the distal interphalangeal joint (swan-neck deformity), or flexion at the proximal interphalangeal joint with hyperextension at the distal interphalangeal joint (boutonnière deformity). A Z-deformity of the thumb can be seen in systemic lupus erythematosus.

Feel

Palpate over each joint line for tenderness or bony or synovial swelling. Squeezing across all the knuckles together can be used as a composite assessment for tenderness of the metacarpophalangeal joints.

Move

Palpate the tendon sheaths during movement to detect crepitus or tendon nodules. Feel the quality of the skin for induration, thickening, or laxity.

Actively make a tight fist with palmar aspect uppermost to see whether all fingers fully flex and estimate strength of grip by observing blanching of the palmar surface of the hand on release of the fist.

Actively make a firm pinch grip between the thumb and fingers individually.

Passively extend the fifth finger to assess for hypermobility.

Actively make a fist.

Release the grip and observe the palm for blanching.

Palpate the metacarpophalangeal joints.

Palpate the proximal interphalangeal joints.

Squeeze across the metacarpophalangeal joints.

Palpate the tendon sheaths.

Assess grip strength.

Assess pinch grip.

Assess for hypermobility of the thumb and wrist.

Assess hyperextensibility of the fifth finger.

BOX 28.7 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM—LOWER EXTREMITY

Observing gait is an important part of assessing the lower limbs. Examination should be done with the person lying on a bench. Measure leg length if a pelvic tilt when standing suggests shortening or with a discrepancy in the position of the medial malleoli with a straightened pelvis. Pain in the hindquarter is often called “hip pain” but can have many origins that need elucidation by examination.

Hip**Look**

Observation of the person walking will have given some information about the hips. Wasting of the buttock or thigh muscles from disuse may be apparent.

Feel

Palpation should be used to clarify the origin of any symptoms. The word *hip* is used to describe symptoms anywhere in the hindquarter.

Tenderness is usually related to tendinitis or bursitis.

Move

With the person supine, actively and then passively flex the hip as far as possible with the knee in flexion to look for contralateral movement.

With the hip passively flexed to 90 degrees, rotate it internally and externally by holding the foot, supporting the thigh, and moving the lower part of the leg inward and outward while being careful to not inflict pain.

Internal rotation is often affected first in disorders of the hip joint.

With the person lying supine and the leg fully extended, hold the contralateral anterior superior iliac spine to prevent movement of the pelvis and passively abduct and adduct the leg.

With the person lying prone or on the side, passively extend the straightened leg.

Assess leg length by the relative position of the medial malleoli with the pelvis straightened.

Hip flexion-active.

Hip flexion-passive-to look for contralateral movement.

Internal rotation.

External rotation.

Abduction.

Adduction.

**Knee****Look**

Observation of the person walking will have given some information about the knees. Wasting of the thigh muscles from disuse may be apparent. Instability may be present. Look for any swelling and its exact site because it may relate to the joint or periarticular structures. Look for any deformity. Typical deformities are fixed flexion, valgus, or varus.

Feel

Palpate for tenderness or swelling and establish the affected structures. Palpate the joint line for tenderness. Assess for articular swelling and effusion by the bulge sign or patella tap (see Fig. 28.5). Palpate for a popliteal cyst.

Move

With the person supine, passively flex the knee as far as possible with the hip in flexion. If the hip is also abnormal, hang the leg over the side of the bench to examine flexion of the knee without hip flexion.

With the person lying supine, fully extend the leg in an attempt to touch the back of the knee onto the bench. Assess passively if the knee will hyperextend.

Stress

Anterior and posterior stability should be tested to assess the cruciate ligaments.

Medial and lateral stability should be tested to assess the collateral ligaments and for loss of joint space.

Knee flexion.

Knee extension.

Stress the cruciate ligaments.

Stress the collateral ligaments.

BOX 28.7 REGIONAL EXAMINATION OF THE MUSCULOSKELETAL SYSTEM—LOWER EXTREMITY—cont'd**Foot and ankle**

- Look** Observe the feet when standing and during walking. Look for a normal longitudinal arch and, during the gait cycle, look for normal heel strike and take-off from the forefoot. Look for any callosities beneath the metatarsal heads and for any swelling and redness of the toes. Swelling of the metatarsophalangeal joints can separate the toes so that daylight becomes visible between them. Look for any deformities. Deformities include pes planus (flattening of the longitudinal arch); pronation of the foot; valgus deformity of the hindfoot (eversion of the subtalar joint); pes cavus (high longitudinal arch); talipes equinovarus; hallux valgus; subluxation of the metatarsophalangeal joints; and "claw," "hammer," and "mallet" deformities of the toes.
- Feel** Symptoms may relate to the joint, periarticular bone, tendons and their sheaths and insertions, or bursae. Palpate for tenderness or swelling and establish the affected structures. Squeeze across the metatarsus, and if tenderness is noted, examine the metatarsophalangeal joints individually.
- Move** Actively flex and extend the ankle. Actively invert and supinate and then evert and pronate the foot. Passively deviate the heel medially (inversion) and laterally (eversion) by grasping the heel between the thumb and index finger of one hand and moving it while anchoring the lower part of the leg with the other hand. Passively rotate the forefoot on the hindfoot by grasping the forefoot between the thumb and fingers while anchoring the heel with the other hand to assess the midtarsal joint. See whether the patient is able to stand on the toes, which requires an intact posterior tibialis tendon.

Metatarsal squeeze.

Ankle flexion.

Ankle extension.

Inversion and supination.

Eversion and pronation.

Subtalar inversion.

Subtalar eversion.

Midtarsal rotation.

Assessing the first metatarsophalangeal joint.

examination is documented most easily on a homunculus. A standardized approach is recommended to denote deformities, restricted movement, joint swelling, and joint tenderness (Fig. 28.7).

Various disease-specific standardized assessments can be used to evaluate conditions such as rheumatoid arthritis, ankylosing spondylitis, or SLE. These conditions are considered elsewhere in this text.

CONCLUDING THE CONSULTATION

Interpretation

The aim of the consultation is to identify the cause of the person's problems, assess their impact and response to any treatment, plan management, and fully discuss this and the expected outcome with the patient.

Making a diagnosis requires integration of the history and findings on examination with knowledge of the possible causes and results of appropriate investigations. Pattern recognition plays a key role (see Chapter 29). Knowing what is likely at different stages of life in different individuals and looking for clues throughout the consultation are important. Because musculoskeletal conditions are common, it must be remembered that multiple pathologic processes are possible.

ANNOTATING THE EXAMINATION FINDINGS

Fig. 28.7 A homunculus can be used to annotate abnormal findings during examination.

Communicating the findings

The most important part of the consultation, especially for the patient, is communication of the findings and conclusions. Ensure that the person feels that all the problems have been listened to, questions answered, and expectations met as far as possible. It is sometimes difficult to explain all of a person's symptoms with precise tissue-based causes, and this can cause

concern and loss of confidence in the physician. Concepts of mechanical back pain and fibromyalgia can be difficult for the person to grasp. This part of the consultation needs the most time but is usually the most hurried part. A specialist nurse can supplement the information that the person wants, and a lot of material about musculoskeletal conditions is available from support organizations such as the Arthritis Foundation or Arthritis Care and through the Internet.

Pattern recognition in arthritis

■ OSVALDO HÜBSCHER

- Pattern recognition is the key to diagnosis of the rheumatic disorders; central questions that need to be asked are as follow:
 - Is a musculoskeletal problem or disease present in another system?
 - Is the condition articular or periarticular?
 - Is the condition mechanical (arthrosis) or inflammatory?
 - Does it affect appendicular or axial structures, or both?
- These questions can be answered from synthesis of data from the history and physical examination:
 - *From the history:* mode of onset, sequence of development of the different features, and the duration and pattern of the symptoms
 - *From the physical examination:* the number, distribution, and pattern of the affected joints or periarticular structures and the nature of any systemic involvement

INTRODUCTION

The history and physical examination are the two most important components of the diagnostic process for patients complaining of musculoskeletal pain, stiffness, or other symptoms.¹ Clinical judgment in interpreting the findings elicited from the history and physical examination should allow the physician to answer several key questions:

- Do the symptoms originate in the musculoskeletal system or in other systems (e.g., neurologic disorders, vascular disease, Pancoast syndrome)?
- Is it an articular or nonarticular process? A substantial number of patients will have localized mechanical problems or nonspecific soft tissue conditions. Muscular syndromes or pain originating in periarticular foci can often mimic an articular origin (sometimes affecting more than one site). Examples are unilateral or bilateral anserine bursitis resembling an intraarticular knee joint disorder and extensor tendinitis of the thumb (de Quervain tenosynovitis) mimicking wrist involvement. Primary bone conditions (e.g., Paget disease, osteoid osteoma, osteomalacia), as well as infiltrative (e.g., lymphomas) and lytic (e.g., metastatic disease, osteitis fibrosa cystica) lesions, may also provoke pain referred to a joint.
- Does the patient have arthralgia or arthritis? Arthralgia refers to pain localized to a joint, whereas arthritis refers to objective evidence of an inflammatory change in the joint. Arthritis is a much more specific sign of an articular disorder.
- Is evidence of other organ involvement present (e.g., systemic connective tissue disorders), or does it appear to be a disorder restricted to the musculoskeletal system (e.g., osteoarthritis)?
- Is the articular problem inflammatory, mechanical, degenerative, or something else?
- Does the disease affect axial or appendicular structures, or both?

Once the physician has established that the disorder originates in the joints, several other aspects of the history and physical examination should be considered to delineate a diagnostic pattern of arthropathy. The attributes of joint involvement that are considered in this section focus on those dominating the clinical picture during the early phases of rheumatologic

disorders, when treatment could be of greater benefit. Moreover, the diagnostic value of pattern recognition will be considered without taking into account other characteristics of the patient (e.g., gender, age, family history, or the presence or absence of extraarticular features of disease) normally contributing to diagnostic certainty.

MODE OF ONSET AND DURATION OF SYMPTOMS

Some arthropathies typically cause an acute onset of pain with the peak intensity being reached within hours or a few days, whereas in others maximum severity is attained gradually (over a period of several weeks or months). The same disorder may have a sudden onset in some patients but be gradual in others. Rheumatoid arthritis (RA), for instance, may be manifested as an acute polyarthritis (especially in the elderly) and psoriatic arthritis as an acute monoarthritis resembling gout, but in most cases both disorders begin insidiously. Examples of disorders with an acute onset also include bacterial arthritis, rheumatic fever, reactive arthritis, sarcoidosis, palindromic rheumatism, and crystal-induced arthritis (the best example being nocturnal attacks of gout). An arthritogenic virus (e.g., rubella virus and hepatitis B virus) may also cause acute synovitis. An insidious pattern is common with osteoarthritis (OA), early-onset pauciarticular juvenile idiopathic arthritis (EOPA-JIA) and the polyarticular-onset type, mycobacterial and fungal arthritis, and most cases of neuropathic arthropathy (Charcot joints).

Arthritic disorders lasting less than 4 to 6 weeks are considered to be self-limited in practical terms, whereas those lasting longer are considered to be chronic. In self-limited arthritic disorders the duration of symptoms and signs may be a valuable discriminating feature. Early episodes of monoarticular gout tend to subside spontaneously after 7 to 10 days and resolution is complete, acute or subacute attacks of pseudogout (calcium pyrophosphate dihydrate crystal deposition disease [CPPD]) may last from 2 to 3 days to 3 to 4 weeks, and most articular or periarticular episodes of palindromic rheumatism disappear within hours to several days with no articular sequelae. Steady inflammation in an individual joint for more than a few days or a week in children is highly unlikely to be due to rheumatic fever.

THE NUMBER OF AFFECTED JOINTS

The clinical pattern may be monoarticular, oligoarticular, or polyarticular, as reflected by involvement restricted to a single, a few, or several joints, respectively.

Although almost any individual arthropathy may begin as monoarthritis, the initial pattern of some disorders is characteristically monoarticular regardless of the subsequent course. In particular, patients with an acute painful synovitis of a single joint and varying degrees of overlying redness represent a challenging subset in clinical rheumatology.^{2,3} Although redness may occur with any acute monoarthritis regardless of the cause, its presence usually evokes a restricted list of possible diagnoses (Table 29.1). The most common are crystal-induced synovitis (including acute calcific periarthritis),⁴ bacterial infectious arthritis (Fig. 29.1), traumatic conditions, psoriatic arthritis, and palindromic rheumatism (in which the joint may have a dark, bluish redness).

Chronic monoarthritis is often the initial manifestation of a variety of joint disorders (Table 29.2) and may or may not spread with time to other joints; histologic elucidation may be necessary to make the correct diagnosis. In a substantial number of patients the cause remains undetermined.⁵

TABLE 29.1

The red-hot joint

Type	Subtypes/examples (if applicable)
Infectious	Bacterial Neisserial (may be preceded by transient polyarticular disease) Mycobacterial Virus Lyme disease
Crystal induced	Gout Calcium pyrophosphate dihydrate crystal deposition disease (pseudogout type) Hydroxyapatite (acute calcific periarthritis)
Traumatic/fracture	
Palindromic rheumatism	
Psoriatic arthritis	
Reactive arthritis	
Bacterial endocarditis	
Sarcoidosis	

TABLE 29.2

Selected causes of chronic monoarthritis

Type	Subtypes/examples (if applicable)
Infectious arthritis	Mycobacterial, fungal, bacterial, viral, Lyme disease
Inflammatory arthritis	Crystal induced Monoarticular rheumatoid arthritis Early-onset pauciarticular juvenile idiopathic arthritis Seronegative spondyloarthritis (ankylosing spondylitis, reactive arthritis, colitic arthritis, undifferentiated spondyloarthritis) Psoriatic arthropathy Foreign body synovitis (e.g., plant thorn synovitis) Sarcoidosis
Noninflammatory arthritis	Osteoarthritis Internal derangement Osteonecrosis Synovial osteochondromatosis Reflex sympathetic dystrophy Hemarthrosis (e.g., coagulopathy, anticoagulants) Neuropathic (Charcot joint) Paget disease Stress fracture Transient regional osteoporosis Juvenile osteochondroses
Tumors	Pigmented villonodular synovitis Lipoma arborescens Synovial metastasis from solid tumors Synovial sarcoma Osteoid osteoma
Undiagnosed	

Involvement of two to four separate joints is referred to as oligoarthritis. In general, rheumatologic disorders manifested as monoarthritis may also be oligoarticular. Despite this overlap, in some cases involvement of two or three joints (rather than one) may significantly narrow the diagnostic spectrum. As an example, lower limb oligoarthritis (especially of the knees and ankles) in an asymmetric fashion is reminiscent of the HLA-B27-associated seronegative spondyloarthropathies.⁶ An asymmetric oligoarthritis affecting scattered distal interphalangeal (DIP), proximal interphalangeal (PIP), and metacarpophalangeal (MCP) joints of the hands characterizes a common subgroup of patients with psoriatic arthritis.

The third articular pattern is one in which polyarticular involvement dominates the clinical picture. A wide variety of inflammatory and noninflammatory disorders, both common and uncommon, may be manifested as polyarthritis (Table 29.3).⁷

TABLE 29.3

Distribution of selected oligoarthritis and polyarthritis

Symmetric	Asymmetric
Inflammatory	
RA, JIA (systemic and polyarticular types) Adult-onset Still disease Systemic lupus erythematosus Mixed connective tissue disease Polymyalgia rheumatica Rheumatic fever (adult onset) Jaccoud arthritis	Ankylosing spondylitis Reactive arthritis Psoriatic arthritis (oligoarticular type) Enteropathic arthritis Undifferentiated spondyloarthritis JIA (pauciarticular types) Palindromic rheumatism
Degenerative/crystal induced	
Osteoarthritis (primary generalized, erosive, and nodal types) CPPD (pseudo-RA type) "Milwaukee shoulder" Hemochromatosis arthropathy	Gout (especially oligoarthritis) CPPD (pseudogout type)
Infectious	
Viral arthritis	Bacterial arthritis Bacterial endocarditis Lyme disease (late phase)
Miscellaneous	
Hypertrophic osteoarthropathy Amyloid arthropathy Myxedematous arthropathy Sarcoid arthritis (acute type) Cancer-associated arthritis	Cancer-associated arthritis Pancreatic disease-associated arthritis

Most asymmetric arthritides may be or are characteristically initially monoarticular. CPPD, calcium pyrophosphate dihydrate crystal deposition disease; JIA, juvenile idiopathic arthritis; RA, rheumatoid arthritis.

Fig. 29.1 The red-hot joint. Septic arthritis of the ring finger metacarpophalangeal joint has resulted in swelling and intense redness of the skin.

IS THE ARTHRITIS SYMMETRIC OR ASYMMETRIC?

This distinction is very helpful in the differential diagnosis of oligoarticular and polyarticular conditions, with RA being the classic example of symmetric arthritis, which denotes simultaneous inflammatory signs in pairs of peripheral joints. Symmetry is not necessarily strict in the hands; the same MCP or PIP joint may not be equally affected in both extremities of patients with RA. Erosive inflammatory OA, pachydermodactyly, parvovirus arthritis, and many cases of systemic lupus erythematosus (SLE) may resemble RA, whereas reactive arthritis, psoriatic arthritis, and polyarticular gout are usually characterized by asymmetric involvement of appendicular joints.

Fig. 29.2 Rheumatic disorders affecting the distal interphalangeal (DIP) joints. (a) Psoriatic arthropathy of two DIP joints and the interphalangeal joint of the thumb, together with nail dystrophy. (b) Osteoarthritis is the most common disorder affecting this segment (Heberden nodes).

TABLE 29.4
Chronic arthropathies with peripheral and axial involvement

Type	Subtypes/examples (if applicable)
Inflammatory	
Spondyloarthritis	Ankylosing spondylitis Reactive arthritis Psoriatic arthropathy (a subset of patients) Enteropathic arthritis Undifferentiated
Juvenile idiopathic arthritis	Systemic and polyarticular onset
Adult-onset Still disease	
SAPHO syndrome	
Noninflammatory	
Osteoarthritis	
Diffuse idiopathic skeletal hyperostosis	
Acromegaly	
Ochronosis	
Spondyloepiphyseal dysplasia	
<i>SAPHO, synovitis, acne, pustulosis, hyperostosis, and osteitis.</i>	

Both symmetric and asymmetric seronegative oligoarthritis and polyarthritis have been described in association with neoplasia in rare cases.⁸

This feature of the articular pattern has obvious limitations: every patient with a symmetric disorder may have an initial asymmetric phase. Table 29.3 lists a number of conditions classified according to the most characteristic pattern.

LOCALIZATION OF AFFECTED JOINTS

Axial involvement

Axial structures include, apart from the spine, centrally located joints such as the sacroiliac, sternoclavicular, and manubriosternal joints and the rest of the chest wall and sometimes the shoulders and hips.

In the presence of peripheral arthritis, one of the most helpful clues in the differential diagnosis is to determine the presence of concomitant axial involvement. Whereas some rheumatologic conditions rarely affect the axial segments (e.g., crystal-related syndromes, systemic connective tissue disorders), a combined pattern is often seen in others (Table 29.4). OA of the spine frequently coexists with appendicular involvement. Diffuse idiopathic skeletal hyperostosis affects mainly the dorsal and lumbar spinal segments and may be accompanied by OA in atypical upper limb joints (elbow, shoulder, MCP).⁹ Patients with ankylosing spondylitis, psoriatic arthritis, reactive arthritis (after both enteric and sexually transmitted infection), and arthritis accompanying inflammatory bowel disease may also exhibit varying degrees of combined axial and peripheral involvement. Polyarticular and systemic-onset juvenile idiopathic arthritis, as well as adult-onset Still disease, commonly affects the apophyseal joints of the cervical spine in addition to peripheral joints. SAPHO syndrome (synovitis, acne,

Fig. 29.3 Acute gout. The first metatarsophalangeal joint is involved at some time in approximately 75% of patients. Desquamation of the skin often occurs.

pustulosis, hyperostosis, and osteitis) is a further example among the much less frequent arthritides.¹⁰

Peripheral involvement

Individual joints, tendon sheaths, and bursae may be affected by a large number of rheumatic disorders. Involvement of some joints, however, may be closely associated with the early phases of a particular disease or group of diseases and thereby facilitate the diagnostic process. Common examples in clinical rheumatology include the following:

- Bilateral and symmetric involvement of small and large joints is typical of RA. The MCP and PIP joints of the fingers and wrists are commonly affected. Distal joints are less frequently involved.
- Exclusive inflammatory DIP joint involvement of the fingers is a relatively infrequent, though important clue to the diagnosis of a subset of patients with psoriatic arthritis. Nodal OA (Heberden nodes) is the most frequently encountered disorder affecting this segment (Fig. 29.2).
- Bilateral bony enlargement of the second and third MCP joints with restricted motion is characteristic of hemochromatosis-related arthropathy.¹¹
- Severe proximal pain (neck, shoulders, and buttocks) with minimal objective findings in an appropriate setting is highly indicative of polymyalgia rheumatica, although the onset of RA in the elderly may be difficult to differentiate from this entity.¹²
- Bilateral shoulder disease with striking joint enlargement (shoulder pad sign) is very typical of amyloid arthropathy.¹³
- Podagra: the metatarsophalangeal joint of the big toe is typically affected during acute gouty attacks (Fig. 29.3). Less frequently, CPPD and other crystalline disorders,¹⁴ as well as OA, psoriatic arthritis, and a wide variety of conditions, may mimic the podagra of gout.¹⁵ The occurrence of “pseudopodagra” is one of the best examples of how the specific site of the index joint, though helpful, can only suggest the diagnosis.

Fig. 29.4 Sausage fingers and toes. (a) Psoriatic arthropathy/dactylitis of the third finger. (b) Reactive arthritis/dactylitis more evident in the second and third toes. Note the nail dystrophy.

- Pain and swelling in the knees and ankles (often asymmetric) may be seen in seronegative spondyloarthritis, including reactive arthritis after infection with *Chlamydia* and enteric organisms.¹⁶ In both of the latter conditions, involvement of the toes is also frequent, and the clinical appearance of dactylitis (“sausage toe”) is most typical. Dactylitis is also very reminiscent of psoriatic arthritis (Fig. 29.4).

SEQUENCE OF JOINT INVOLVEMENT

Clinical involvement of joints may follow three major patterns: additive, migratory, and intermittent. An additive pattern refers to the involvement of additional joints while the previous joints remain symptomatic. Polyarticular OA, reactive arthritis, and RA are typical examples of this progressive sequence.

A migratory pattern means that the process ceases or abates in one joint while simultaneously or immediately thereafter starting in a previously normal joint. Whipple disease and neisserial arthritis may be manifested as a migratory arthritis and tenosynovitis, and the fleeting arthritis of rheumatic fever in children is a classic example.

The intermittent rheumatologic disorders are characterized by complete remission of symptoms and signs until the next recurrence in the same or other joints. No evidence of active disease or residual signs can be detected during intervals. Crystal-induced arthritis, familial Mediterranean fever, Muckle-Wells syndrome, the arthritis seen in Whipple disease, and palindromic rheumatism usually follow this pattern for years with asymptomatic periods that vary in length. Adult-onset Still disease may also run a polycyclic clinical course.¹⁷

LOCAL PATTERN OF JOINT DISEASE

Some local signs may be of great diagnostic help. In the same manner as the presence of redness often suggests a particular group of diagnoses (see earlier), the occurrence of skin desquamation when the inflammation declines is suggestive of acute gouty monoarthritis. Additional findings that may be of diagnostic value include the following:

- Enlargement of a given individual joint may be symmetric or asymmetric (more obvious in the fingers). Fusiform swelling of the PIP joints is typical of RA, as opposed to Heberden nodes, erosive OA, chronic sarcoidosis, and tophaceous gout, which often produce asymmetric enlargement of the affected joint.
- The local signs of inflammation may extend beyond the anatomic limits of the joint. This feature may be a major diagnostic contribution, as illustrated by the presence of dactylitis. A diffusely painful swollen hand or foot may indicate reflex sympathetic dystrophy syndrome in that extremity (Fig. 29.5). Bilateral symmetric puffy swelling of hands and fingers (and sometimes the feet) may be seen in the early phases of systemic sclerosis and mixed connective tissue disease (Fig. 29.6). In a totally different clinical context, diffuse swelling of both hands with pitting is a conspicuous feature of the syndrome of “remitting seronegative symmetric synovitis with pitting edema” (Fig. 29.7).¹⁸

Fig. 29.5 Reflex sympathetic dystrophy syndrome. Diffuse edematous swelling of the entire right hand is evident.

Fig. 29.6 Swollen hands in mixed connective tissue disease. The presence of symmetric puffy hands is a common early finding. Similar changes are often seen in the early stages of scleroderma.

Fig. 29.7 Remitting seronegative symmetric synovitis with pitting edema. Note the massive acute painful edema of both hands in an 80-year-old man.

Fig. 29.8 Flexion contractures of all fingers in carcinoma-associated fasciitis. Painful swelling and contractures of both hands developed in a 50-year-old woman secondary to marked hardening and thickening of the palmar fascia. Palmar erythema is also present. Investigations revealed ovarian carcinoma, the most commonly associated neoplasm in these patients.

- Symmetric enlargement of the hands and feet associated with variable degrees of pain is seen from time to time by rheumatologists. Digital clubbing and local signs of inflammation may or may not be prominent. Primary or secondary hypertrophic osteoarthropathy,¹⁹ acromegaly, and the rare thyroid acropachy should be considered when encountering these cases.
- Flexion contractures of the fingers (plus other segments in some cases) as a result of structural changes in soft tissues lead to a number of clinical diagnoses apart from systemic sclerosis and eosinophilic cutaneous fibrosis. β_2 -Microglobulin amyloidosis, nephrogenic systemic fibrosis (both entities occurring in patients undergoing hemodialysis), diabetic cheiroarthropathy, and the syndrome of cancer-associated palmar fasciitis are among the diagnostic options (Fig. 29.8).²⁰

THE CLINICAL VALUE OF PATTERNS OF ARTHROPATHY

Evidence of some distinct articular patterns focuses the spectrum of diagnostic options and reduces unnecessary diagnostic testing.²¹ These patterns are not diagnostic per se, and they must always be viewed only as a rough guide for various reasons.

First, unrelated arthropathies may share one or more clinical patterns. As an example, EOPA-JIA, tuberculous arthritis, and foreign body arthritis

Fig. 29.9 Early-onset pauciarticular juvenile idiopathic arthritis in a young girl with monoarthritis. This patient had associated asymptomatic iridocyclitis. In some cases, synovial biopsy is mandatory to exclude other disorders.

Fig. 29.10 Gouty attack superimposed on a Heberden node. The clinical combination may be found in elderly patients treated with diuretics, as seen in the distal interphalangeal joint of the right index finger in this 78-year-old woman. Note the mild desquamation of the overlying skin.

(e.g., plant thorn synovitis)²² may all give rise to a chronic monoarthritis of the knee (Fig. 29.9). Both gout and pseudogout can mimic septic arthritis in the setting of febrile acute monoarthritis or polyarthritis.²³

Second, some major arthritides have more than one mode of onset. It should be remembered, for example, that chronic or intermittent monoarthritis and oligoarthritis (with no involvement of the small joints of the hands) may occasionally dominate the early course of RA before symmetric polyarthritis evolves. The same finding may also precede the appearance of typical inflammatory low back pain in patients with ankylosing spondylitis. Moreover, CPPD has many clinical patterns, with pseudogout and pseudoosteoarthritis being the most frequent.²⁴

Third, the articular pattern may change with time in the course of a single disorder. In these cases the correct diagnosis is facilitated when the patient is seen during the “typical” phase of the disease and may be hampered during the “atypical” phases. Early monoarticular gout is easy to suspect. In late stages it may be manifested as a chronic additive, relatively symmetric polyarticular disease, thereby leading to confusion with RA.²⁵ Finally, a single clinical pattern of joint disease may correspond to more than one diagnosis. Chronic gout superimposed on Heberden nodes²⁶ and the coexistence of crystals and infection in cases of subacute monoarthritis²⁷ are examples of this clinical situation (Fig. 29.10).

Fourth, a significant number of patients with peripheral arthritis do not fall into a specific diagnosis and may be described as having an undifferentiated peripheral arthritis (UPIA). Patients may persist with UPIA, progress to a specific diagnosis, or enter remission. An algorithm has been proposed to provide an approach to reach a diagnosis.²⁸

The combination of features just analyzed can often contribute to accurate diagnosis of an arthropathy. Diagnostic refinement may require the addition of laboratory studies, joint fluid examination, imaging techniques, and other methods. The more varied the articular patterns possible in a

given arthropathy, the more necessary complementary studies become. Systemic vasculitis, SLE, bacterial endocarditis, human immunodeficiency virus infection, solid tumors and leukemia, Behçet syndrome, sarcoidosis, relapsing polychondritis, and pancreatic-associated arthritis are examples of disorders in which several patterns of arthropathy have been described and a panoply of investigations may be required in addition to the physical findings. However, a careful history and physical examination remain the cornerstone of diagnostic evaluation of all patients with rheumatologic complaints.

Role of laboratory tests in rheumatic disorders

■ EUGEN FEIST ■ GERD-RÜDIGER BURMESTER

- In rheumatic diseases laboratory tests contribute significantly to diagnosis, which should always be based on clinical findings. Measurement of biomarkers can also be useful for monitoring of treatment efficacy and safety as well as for stratification of patients to predict prognosis and treatment response.
- Sensitivity and specificity of virtually all biomarkers is limited, and therefore the laboratory diagnostics should be guided by the clinical picture.
- Laboratory markers provide different positive or negative predictive values; thus they can be used to exclude a disease in cases of a normal result or to support the clinical diagnosis in cases of a pathogenic result.

INTRODUCTION

In this chapter the focus is on commonly used laboratory tests that are relevant to major disorders seen by rheumatologists. Because laboratory test results are commonly part of the classification and diagnostic criteria, it is important to understand some key conceptual issues before using these tests in making diagnostic and treatment decisions.

Sensitivity is the percentage of *true positives* correctly identified. For example, if 60% of patients with rheumatoid arthritis (RA) have a positive result on a test for rheumatoid factor (RF) immunoglobulin M (IgM), the sensitivity of RF IgM for RA is 60%.

Specificity, on the other hand, is the percentage of *true negatives* correctly identified. For example, if 80% of patients without RA do not have RF IgM, then the specificity of RF IgM for RA is 80%.

The **likelihood ratio** (LR) incorporates both the sensitivity and specificity of a given test and provides a direct estimate of how much a test result will change the odds of having a disease. The likelihood ratio for a positive result (LR+) indicates the increase in the odds of having the disease when a test result is positive. The likelihood ratio for a negative result (LR-) indicates the decrease in the odds of having the disease when a test result is negative. The pretest odds is the likelihood that the patient has a specific disease before testing and is usually related to the prevalence of the disease. The likelihood ratio can be combined with information about the prevalence of the disease, characteristics of the patient pool, and information about the particular patient to determine the posttest odds of disease.

The more frequently a given condition, or a positive laboratory test result, occurs in the healthy population, the more likely that the condition will be diagnosed. Clinicians only seldom appreciate the importance of disease frequency (the pretest probability in Bayesian terms) in making a diagnosis.¹ The prevalence of positive results on a certain blood test in the healthy population must be known for the results of any rheumatologic screening test to be interpreted correctly (Table 30.1).

The concepts of false-negative and false-positive results are the converse of sensitivity and specificity, respectively, but are useful in clinical decision-making. False-positive results on antinuclear antibody (ANA) tests are one frequent reason for rheumatology consultations. For example, the prevalence of systemic lupus erythematosus (SLE) in the general population depends on the geographic region and is around 1 in 2000 to 1 in 10,000, whereas 1 in 20 healthy individuals have a usually weakly positive result in

ANA screening. Thus, given the frequency of nonspecific musculoskeletal symptoms in the general population, only a minority of such patients, even if they test positive for ANA, have SLE (Table 30.2).^{2,3}

Problems with false-negative results are more unusual but may have serious consequences. For example, patients with vasculitis and other life-threatening rheumatic diseases may develop irreversible end-organ damage because the diagnosis has been erroneously ruled out just on the basis of negative laboratory results.

Finally, there is always the risk of measurement error in any test, and this applies to all laboratory tests in rheumatic diseases. Whenever clinical signs and symptoms do not match the laboratory test results, the tests should be considered possibly in error and should be repeated.

LABORATORY TESTS IN RHEUMATIC DISEASES

The most common use of blood cell counts and measurements of biochemical markers is to monitor adverse effects of the various immunosuppressive medications used for the treatment of rheumatic conditions. In this context, detailed guidelines for monitoring treatment with various traditional as well as biologic disease-modifying antirheumatic drugs (DMARDs) were developed by different rheumatologic societies. Markers of the acute-phase response are mainly useful for evaluation of disease activity and differentiation of infectious complications.⁴

Blood panel**White blood cells**

Increased concentrations of neutrophils typically are seen in bacterial infections (e.g., infectious arthritis, septicemia, pneumonia) but also in active phases of rheumatic diseases such as RA and vasculitides. In patients undergoing immunosuppressive treatment, the presence of neutropenia should always raise suspicion of drug-related bone marrow suppression. In contrast, neutropenia in association with splenomegaly is a characteristic feature of active Felty syndrome. Lymphocytosis is present during several viral infections, whereas lymphopenia is commonly seen in active phases of SLE as well as with immunosuppressive drug treatment.

Eosinophilia, commonly seen in patients with allergies and parasitic infections, also is a typical feature of eosinophilic granulomatosis with polyangiitis (formerly known as *Churg-Strauss syndrome*) and eosinophilic fasciitis (Shulman syndrome). Of note, eosinophil blood counts are very sensitive to glucocorticoid treatment and show a rapid normalization.

Platelets

Thrombocytosis can accompany active phases of autoimmune diseases such as RA, whereas thrombocytopenia can be related to the presence of anti-thrombocyte antibodies, for example, in active SLE. Furthermore, decreased thrombocyte counts raise suspicion of drug-induced toxicity. To differentiate these conditions, examination of a peripheral blood smear and ultimately bone marrow aspiration are useful. Examination of bone marrow aspirates reveals the number and appearance of megakaryocytes and is the definitive test for many disorders causing marrow failure. However, normal number and appearance of megakaryocytes does not always indicate normal platelet production. For example, in patients with immune thrombocytopenic purpura, platelet production frequently is decreased, or not appropriately increased, despite the presence of normal-appearing megakaryocytes.⁵ If the bone marrow is normal but the spleen is enlarged, increased splenic sequestration is the likely cause of thrombocytopenia; if the bone marrow is normal and the spleen is not enlarged, excess platelet destruction is the

■ TABLE 30.1

Laboratory tests used in inflammatory rheumatic diseases: likelihood of disease in patients with positive test results

Blood test	Suspected disease	Patients with positive result	Prevalence of positive result in normal persons	Disease prevalence	Likelihood of disease if result is positive	Likelihood of disease if result is positive and joint pain is present
Rheumatoid factor	Rheumatoid arthritis	80/100	2/100	1/100	1/2	1/1.5
Antinuclear antibodies	Systemic lupus erythematosus	99/100	1/100	1/2000	1/20	1/5
HLA-B27	Ankylosing spondylitis	90/100	6/100	1/300	1/18	1/4.8 (1/3 for back pain)
Elevated uric acid	Gout	80/100	5/100	1/200	1/10	1.3

Diagnosis of rheumatic diseases

Diagnosis	History and physical examination	Blood tests	Radiographs	Synovial fluid
Rheumatoid arthritis	Synovitis Morning stiffness	RF or ACPA in ~80% Elevated ESR in 50%-60%	Demineralization Erosions Joint space narrowing	Inflammation WBC > 10,000/mm ³
Systemic lupus erythematosus	Multisystem disease	ANA in >99% DNA antibodies in 60%-75%	Generally nondestructive arthritis	Mild inflammation
Axial spondyloarthritis	Back pain Axial involvement	HLA-B27 in ~90%	Sacroiliitis Vertebral squaring	Inflammation WBC 5000-20,000/mm ³
Gout	Recurrent attacks	Uric acid elevated in 75%-90%	Erosions, cysts	Negatively birefringent crystals on microscopy
Osteoarthritis	Pain ± swelling ± limited motion	Nonspecific abnormalities	Joint space narrowing Osteophytes	Noninflammatory WBC < 10,000/mm ³
Systemic sclerosis	Skin tightness proximal to metacarpophalangeal joints Facial skin tightening	ANA in >90% with HEp-2 cells	± Pulmonary fibrosis ± Esophageal dysmotility ± Calcinosis	Nonspecific
Polymyositis	Muscle weakness ± pain	CPK elevated in 80%, ANA and myositis-specific antibodies	Not helpful	Nonspecific

ACPA, anti-citrullinated peptide antibodies; ANA, antinuclear antibodies; CPK, creatine phosphokinase; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; WBC, white blood cell count. Adopted from Pincus T. Laboratory tests in rheumatic disease. In: Klippel JH, Dieppe PA, editors. *Rheumatology*. 2nd ed. London: Mosby International; 1997, p. 10.1-10.8.

likely cause. Some patients may have platelet dysfunction; a drug cause is suspected if symptoms began only after patients started taking a potentially causative drug. Some medications such as nonsteroidal antiinflammatory drugs (NSAIDs) can interfere with platelet function and lead to bleeding complications.

A hereditary cause is suspected if there is a lifelong history of easy bruising and bleeding after tooth extractions or surgery. In the case of a suspected hereditary cause, von Willebrand antigen and factor activity studies are performed.

Hemoglobin

Anemia in rheumatic diseases most commonly reflects decreased production of red blood cells in the bone marrow due to continued inflammation, with increased hepcidin production leading to disturbed iron metabolism. Anemia of chronic disease is commonly normocytic and normochromic; however, microcytic hypochromic anemia also can be associated with chronic disease. Microcytic hypochromic anemia is commonly seen with iron deficiency and other conditions such as thalassemia and lead poisoning. Macrocytic anemia, commonly caused by vitamin B₁₂ deficiency, folate deficiency, liver disease, and hypothyroidism, is not common in rheumatologic conditions except with methotrexate treatment. Hemolytic anemia is not uncommon, especially in active SLE with detection of antierythrocyte antibodies and in other immune complex-mediated conditions. Anemia due to chronic or acute gastrointestinal bleeding is also a frequent adverse effect of NSAIDs, with glucocorticosteroids contributing to an increased risk.

BIOCHEMICAL TESTING

Liver function tests

Liver function tests should be ordered before and after initiation of treatment with certain antirheumatic drugs (including NSAIDs as well as traditional and biologic DMARDs) to monitor for adverse effects. Measurement of aspartate aminotransferase and alanine aminotransferase is included in guidelines or recommendations for monitoring treatment with all immunosuppressive medications.⁶ Albumin levels can also be measured when chronic liver disease or damage to the liver from medications is suspected. There is evidence to suggest that abnormal results on liver function tests seen with methotrexate therapy in RA may not be as frequent as previously suggested, with very few patients discontinuing methotrexate treatment because liver function test result abnormalities over 10 to 15 years of use.^{7,8}

Alkaline phosphatase

Alkaline phosphatase is made mostly in the liver and in bone, with some produced in the intestines and kidneys. It also is made by the placentas of pregnant women. Conditions that cause rapid bone growth (puberty), bone disease (osteomalacia or Paget disease), hyperparathyroidism, or liver cell damage can lead to increases in alkaline phosphatase levels. Values of 1.5 to 3.0 times the upper limit of normal are consistent with a hepatocellular cause (viral infection, drug toxicity, alcohol), whereas values more than 3.0

times the upper limit of normal are usually associated with biliary involvement. Bone involvement can be found at any alkaline phosphatase level.

Kidney function tests and urinalysis

Kidney function tests are routinely performed before and after initiation of treatment with antirheumatic drugs (including NSAIDs as well as certain traditional and biologic DMARDs) to monitor for adverse effects. For this purpose, creatinine levels or creatinine clearance provides sufficient information. Of note, disturbed kidney function is associated with a high risk of methotrexate accumulation causing toxic effects. Connective tissue diseases and systemic vasculitides are frequently associated with kidney involvement causing glomerular and interstitial nephritis. In cases of suspected nephritic or nephrotic syndrome, urine tests and frequently kidney biopsy are standard procedures. Urinalysis is also useful for monitoring of kidney involvement and should include detection and quantification of proteins as well as of hematuria and leukocyturia.

Uric acid

Uric acid measurement is commonly included in the workup of patients with arthritis, and level may be elevated in 90% of patients with gout. Yet healthy people can have elevated levels as well, and the definitive diagnosis of gout depends on demonstration of uric acid crystals in synovial fluid (Fig. 30.1). In monitoring response to uric acid-lowering therapy, low levels of uric acid (usually less than 5 to 6 mg/dL) should be the goal to reduce the risk of recurrent gout attacks.

Calcium and vitamin D

Determination of calcium and vitamin D levels is part of the workup for osteoporosis and high or low bone turnover states and may be considered in patients at risk of these conditions and for monitoring of treatment. Calcium absorption, use, and excretion are regulated and stabilized by a feedback loop involving parathyroid hormone and vitamin D. Conditions and diseases that disrupt calcium regulation can cause inappropriate acute or chronic elevations or decreases in calcium and lead to symptoms of hypercalcemia or hypocalcemia. Renal insufficiency or failure, symptoms of hypercalcemia (e.g., fatigue, weakness, loss of appetite, nausea, vomiting, constipation, abdominal pain, urinary frequency, and increased thirst) or hypocalcemia (e.g., muscle cramps or tingling in the fingers), gastrointestinal disease leading to poor absorption, thyroid disease, malignancies, and poor nutrition may be reasons for monitoring calcium levels. Monitoring may also be needed during vitamin D supplementation.

In the past 25 years, more than 50 metabolites of vitamin D have been described. To date, only a few of these have been quantified in blood, but this has widened our understanding of the pathologic role that altered vitamin D metabolism plays in the development of diseases of calcium homeostasis. Currently, awareness is growing of the prevalence of vitamin D insufficiency in the general population in association with an increased risk of several diseases. However, for many researchers, it is not clear which vitamin D metabolites should be quantified and what the information gained from such an analysis tells us. Two metabolites—25-hydroxyvitamin D and 1,25-dihydroxyvitamin D—have received the most attention. The need for measuring serum levels of 1,25-dihydroxyvitamin D is limited, and this metabolite therefore should not be considered as part of the standard vitamin D testing regimen. On the other hand, serum levels of 25-hydroxyvitamin D provides the single best assessment of vitamin D status, and thus measurement of this metabolite should be the only vitamin D assay typically performed.⁹

Fig. 30.1 Uric acid crystals in synovial fluid.

Acute-phase reactants

The acute-phase response occurs in a wide variety of inflammatory conditions, including various infections, trauma, malignancies, inflammatory rheumatic disorders, and certain immune reactions to drugs.¹⁰ Currently, the most widely used laboratory tests to monitor inflammation are the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level. Of note, ESR levels are usually physiologically higher in females and also increase with age and during pregnancy. CRP levels in particular have been reported to be higher among obese patients.

The acute-phase proteins are mainly produced by hepatocytes upon stimulation by cytokines (e.g., interleukin-6, interleukin-1, and tumor necrosis factor). The most important acute-phase proteins whose levels increase during inflammation (positive reactants) are CRP, fibrinogen, α_1 -antitrypsin, ferritin, haptoglobin, ceruloplasmin, serum amyloid protein A, and several complement components, especially C3. In inflammatory conditions, increased plasma levels of fibrinogen and immunoglobulins as well as a frequently associated anemia can increase the ESR. In patients with polycythemia or chronic lymphocytic leukemia, a lower ESR is typical.

Serial measurements of ESR and CRP are valuable for monitoring the level of inflammation in patients with disorders such as RA. However, in RA some patients can show signs of clinical disease activity but have normal CRP and ESR values.¹¹ In addition, up to 40% of patients with RA have a normal ESR and/or CRP level at initial presentation.¹² In each instance, the clinical picture should be the determining factor in decision-making regarding treatment. It is essential to note that ESR is an indirect measure of acute-phase protein concentrations. Although CRP concentrations may increase and decrease very rapidly, ESR values change slowly upon control of inflammation.

In patients receiving immunosuppressive treatment, CRP levels may not show an adequate increase when infection is present. Clinicians should be aware of this problem, which seems to be more marked with treatment involving biologics such as the interleukin-6 receptor antagonist tocilizumab, and should rely on clinical examination and imaging tools.

SEROLOGIC TESTING

Autoantibodies

Testing for autoantibodies is frequently used in the diagnosis of rheumatic conditions and sometimes for monitoring of disease activity. Some of these autoantibodies are more specific for one disease, whereas others can be found in several diseases. Both of these categories of autoantibodies may be valuable tools in the clinical workup. Research into autoantibodies has yielded considerable information about the pathogenesis of various rheumatic conditions, but serologic testing for autoantibodies in clinical practice generally remains more an adjunct to diagnosis and management rather than a precise clinical guide.

Rheumatoid factor

Rheumatoid factor (RF) is the traditional designation for autoantibodies directed at the Fc γ chains of IgG molecules. In clinical practice, laboratories tend to test only for IgM RF, but RF can belong to all major immunoglobulin classes (IgG, IgA, IgM) and in some cases IgD and IgE as well. In peripheral circulation, however, the main immunoglobulin classes of RF that can be easily detected are IgA and IgM RFs.

Today enzyme-linked immunosorbent assay (ELISA) and nephelometric assays have become the most common methods for quantifying RF. IgM RF is produced in many chronic inflammatory conditions (long-standing infections such as bacterial endocarditis, hepatitis B and C, tuberculosis, and chronic bronchitis, but also in fibrosing alveolitis and silicosis). Thus RF is not specific for a particular rheumatic disease such as RA. It can also be seen in 5% to 6% of the elderly in the normal population.

The main indications for RF testing in diagnosis are suspicion of RA or Sjögren syndrome, but RF also commonly appears in mixed connective tissue disease, SLE, cryoglobulinemia, and the polyarticular-onset form of juvenile inflammatory arthritis. It is thus apparent that the specificity of RF in differentiating RA from some other rheumatologic conditions is poor. However, with higher titers of RF the specificity increases, and RF testing becomes a more useful laboratory tool. Higher titers are also associated with more aggressive and erosive disease. Of note, 20% to 30% of RA patients test negative for RF and yet have the clinical picture with a potentially poor prognosis when not treated. RF may appear up to several years before the onset of clinical RA. With effective treatment, RF titers can decrease, which is especially typical for B cell-directed therapy with rituximab.

Antibodies to citrullinated protein and peptide antigens

In 1964 antibodies directed to keratohyaline granules of human buccal mucosa cells were described as a specific marker for RA. They were termed *antiperinuclear factor* (APF). Several years later antibodies reacting with upper mucosal cells of the esophagus, so-called antikeratin antibodies (AKAs), were found that had a prevalence in and specificity for RA similar to those of APF. In the late 1990s anti-citrullinated vimentin (anti-Sa) antibodies were described in Canada and anti-citrullinated peptide antibodies (ACPAs) were described in Holland and France. All these antibodies (APF, AKA, anti-Sa, ACPA) have now been shown to target citrullinated parts of proteins such as filaggrin in buccal mucosa, keratin in esophagus, vimentin in macrophages, and fibrin in the RA-affected joint.

Citrullination is the result of deimination of arginine residues in these proteins by activation of Ca^{2+} -dependent peptidylarginine deiminase enzymes during inflammation-induced apoptosis (programmed cell death). Leakage of these active enzymes into cells or onto synovial structures causes citrullination of proteins in many types of synovial inflammation. However, typically only RA patients react to such modified proteins by producing significant amounts of ACPAs. This is likely to depend on the specific presentation of citrullinated peptides to T cells by shared epitope motifs on HLA-DR molecules.

ACPAs can be detected by ELISA and immunoblotting methods using citrullinated proteins or peptides.¹³ The use of a cyclic citrullinated peptide has become the most widely used surrogate antigen for detection of ACPA. Other identified citrullinated autoantigens in RA, such as citrullinated vimentin or mutated citrullinated vimentin, can also be used for detection of ACPA. The sensitivity of the ACPA test is around 50% to 60% at the onset of RA and can rise as high as 85% later in the course of the disease. Several studies have demonstrated the presence of ACPAs up to a decade before the onset of clinical disease.¹⁴ When found in patients with early undifferentiated arthritis, ACPAs predicts later development of classic erosive RA. They are especially prevalent in RF-positive patients but can be found in around 25% of RF-negative RA patients as well.

The ACPA test is helpful in discriminating between RA and psoriasis with erosive arthritis and also between RA-associated and hepatitis C-associated polyarthritis. Yet in the setting of a positive RF test result and typical clinical findings of RA, a positive ACPA test result adds little,¹⁵ especially once a decision to treat has been made, which should be the course of action for any patient suspected of having RA (Table 30.3). Accumulating data suggest that patients seropositive for ACPAs and/or RF may respond better to rituximab. Recently an association between ACPA positivity, HLA-DR alleles, and smoking has been shown in different cohorts.¹⁶

Antinuclear antibodies

ANA testing serves as a screening tool for connective tissue diseases. However, ANAs are seen in individuals with many rheumatologic conditions as well as in many healthy people (Table 30.4). They are generally detected by indirect immunofluorescent (IIF) techniques using monolayers of HEP-2 cells. Subsequently, differentiation of a positive ANA result should be performed using solid-phase immunoassays such as ELISA. ANAs are reported in terms of titers (e.g., 1:320, which is usually also the cutoff for positive results) and staining patterns (e.g., homogeneous or speckled).

The presence of ANAs is a serologic hallmark of connective tissue disorders such as SLE, Sjögren syndrome, mixed connective tissue disease, systemic sclerosis, and undifferentiated connective tissue disease, as well as of autoimmune hepatitis. However, finding antibodies by itself does not

signify disease, because healthy people (especially family members of patients with connective tissue diseases, elderly individuals, and patients using drugs such as sulfasalazine and isoniazid) can show clinically irrelevant positive ANA reactivity.

A high titer increases the likelihood that the presence of antibodies is related to an autoimmune disease. In such cases further workup with testing for the specific antigenic target such as anti-double-stranded DNA (dsDNA), anti-Ro (SS-A), anti-La (SS-B), and antiribonucleoprotein is indicated. In patients in whom a diagnosis cannot be made based on clinical symptoms, watchful waiting is recommended.

ANAs also produce a wide range of staining patterns, which should guide the further serologic differentiation (Figs. 30.2 to 30.4).

Fig. 30.2 Antinuclear antibody homogeneous staining.

Fig. 30.3 Antinuclear antibody speckled staining.

TABLE 30.4
Frequency of antinuclear antibodies in autoimmune and nonrheumatic diseases

	Sensitivity (%)
Autoimmune disease	
Systemic lupus erythematosus	95-100
Systemic sclerosis	60-80
Mixed connective tissue disease	100
Polymyositis/dermatomyositis	60
Rheumatoid arthritis	50
Rheumatoid vasculitis	30-50
Sjögren syndrome	40-70
Drug-induced lupus	90
Discoid lupus	15
Pauciarticular juvenile chronic arthritis	70
Nonrheumatic diseases	
Hashimoto thyroiditis	45
Graves disease	50
Autoimmune hepatitis	50
Primary pulmonary hypertension	40

Fig. 30.4 Antinuclear antibody centromere staining.

Anti-double-stranded DNA antibodies

Anti-DNA antibodies target complexes of single- or double-stranded DNA and protein, producing a homogeneous pattern in ANA IIF with positively reacting chromosomes in metaphase. Although anti-dsDNA antibodies are a specific marker for SLE, anti-single-stranded DNA (ssDNA) antibodies represent a nonspecific finding. A positive result for anti-dsDNA antibodies in ANA or ELISA screening must be confirmed by *Crithidia luciliae* IIF or Farr assay, which provides higher specificity.

Anti-dsDNA antibody testing is very specific (95%) but not as sensitive (70%) for SLE, which makes the test result part of the classification criteria for SLE. Anti-dsDNA antibodies also might have a pathogenic role in SLE nephritis and are commonly associated with disease activity in lupus nephritis. The usual picture in active SLE nephritis is increased anti-dsDNA antibody along with decreased C3 and C4, with levels of all tending to normalize with control of active kidney disease.

Anti-Sm and anti-U1 ribonucleoprotein antibodies

Anti-Sm and anti-U1 ribonucleoprotein (RNP) antibodies are directed against the spliceosome and produce a coarse speckled pattern in ANA IIF, with the nucleoli spared. These antibodies can be confirmed using solid-phase immunoassays such as ELISA. Anti-Sm antibodies are found almost exclusively in SLE patients, are detected in 10% to 40% of these patients, and are part of the ACR classification criteria. When the test result is negative it is not helpful in ruling out SLE, but the presence of these antibodies is a very strong piece of evidence of possible SLE.

The presence of anti-U1 RNP antibodies, especially at high titers, is very typical for mixed connective tissue disease and is a prerequisite for diagnosis. Furthermore, anti-U1 RNP antibodies, usually at lower titer, are found in 40% to 60% of SLE patients.

Anti-Ro (SS-A) and anti-La (SS-B) antibodies

The targets of anti-Ro (SS-A) and anti-La (SS-B) antibodies are nuclear and cytoplasmic RNPs. These antibodies produce a fine speckled pattern in ANA IIF, with staining of the nucleoli as well. Anti-Ro and anti-La antibodies are part of the classification criteria for Sjögren syndrome but also are frequently detectable in SLE patients. They have been particularly associated with subacute cutaneous lupus and photosensitivity. Anti-Ro and anti-La antibodies have also been associated with neonatal lupus and congenital heart block because they cross the placental barrier. Therefore, during pregnancy, the fetus should be screened for congenital heart block by ultrasonography, and newborns of antibody-positive mothers should avoid sunlight exposure during the first weeks of life.

Anticentromere and anti-Scl-70 antibodies

Anticentromere and anti-Scl-70 autoantibodies are the specific and most frequent markers for systemic sclerosis, each detectable in up to 40% of patients. Anticentromere antibodies produce a typical pattern in ANA IIF by staining the centromere region of chromosomes. The target of anti-Scl-70 is topoisomerase I, and it shows a nucleolar and nucleoplasmatic staining as well as positively reacting chromosomes in metaphase. The presence of anti-Scl-70 antibodies should be confirmed using solid phase immunoassays, but the ANA pattern of anticentromere antibodies is pathognomonic. Interestingly, these two antibody types do not occur in the same patient and are associated with distinct clinical pictures. Anticentromere antibodies are more frequently observed in the context of slowly progressive scleroderma and pulmonary hypertension. Patients who test positive for anti-Scl-70 typically have systemic sclerosis and pulmonary as well as esophageal organ manifestations.

Antiphospholipid antibodies

Antiphospholipid antibodies bind to certain serum proteins complexed to phospholipid molecules.¹⁷ The assays most widely used to detect antiphospholipid antibodies are the anticardiolipin assay (ELISA) and the lupus anticoagulant (also called *lupus inhibitor*) functional test. One can screen for functionally procoagulant antiphospholipid antibodies by measuring activated partial thromboplastin time, which is abnormally prolonged in their presence.

Antiphospholipid antibodies were originally detected when false-positive results for syphilis were found using the Wassermann reaction. Subsequently, positive reactivity on the anticardiolipin ELISA and the lupus anticoagulant test was shown to depend on binding of autoantibodies to a serum cofactor, which in the case of the anticardiolipin ELISA is β_2 -glycoprotein I and in the lupus anticoagulant assay may be either β_2 -glycoprotein I or prothrombin.

Lupus anticoagulant is an inappropriate name for the procoagulant autoantibodies because they appear not only in SLE but also in other autoimmune diseases and in so-called primary antiphospholipid syndrome. These are patients experiencing venous or arterial thrombotic events, recurrent fetal loss, and thrombocytopenia in the absence of clinical features of another chronic inflammatory rheumatic disorder. The name also is misleading because lupus anticoagulants are not anticoagulants but procoagulants. They block the assembly of the prothrombinase complex, which gives rise to prolonged results on coagulation assays *in vitro* (e.g., prolonged activated partial thromboplastin time, dilute Russell viper venom time, and kaolin clotting time). This abnormality cannot be corrected by mixing the patient plasma 1:1 with normal plasma, whereas this mixing corrects clotting properties in patients with coagulation factor deficiencies.

Anticardiolipin antibodies are detected by ELISA using cardiolipin-coated microtiter plates that are then flooded with diluted bovine serum to secure binding of bovine proteins to the phospholipid. The most important phospholipid-binding protein attaching to the cardiolipin is β_2 -glycoprotein I, which acts as a cofactor in the test. Autoantibodies to β_2 -glycoprotein I and to the cardiolipin- β_2 -glycoprotein I complex give rise to positive results of importance for diagnosing a procoagulant state, whereas antibodies directed at the cardiolipin itself show no such relationship. Antibodies to the naked cardiolipin appear transiently in several infections and permanently in syphilis. The antibodies may belong to all three major immunoglobulin classes, but IgG anticardiolipin antibodies are those most closely related to procoagulant activity and thus the presence of lupus anticoagulant activity. To be able to discriminate between diagnostically important anticardiolipin antibodies, it is now common to search for specific anti- β_2 -glycoprotein I antibodies using ELISA plates coated with purified β_2 -glycoprotein I protein. The presence of anti- β_2 -glycoprotein I antibodies correlates better with a positive lupus anticoagulant test result and with manifestations of antiphospholipid syndrome. The diagnostic criteria of antiphospholipid syndrome are fulfilled by the presence of a clinical criterion (vascular occlusions and/or pregnancy morbidity) and a positive laboratory test result (with confirmation after 12 weeks).

Antineutrophil cytoplasmic antibodies

Antineutrophil cytoplasmic antibodies (ANCA) represent a subgroup of neutrophil-specific autoantibodies. They are commonly directed to the azurophil granule proteins myeloperoxidase (MPO) and proteinase 3 (PR3). ANCAs are characteristic of patients with necrotizing vasculitides such as granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). In IIF assays, ANCA directed at PR3 typically gives rise to a coarse granular fluorescence pattern in the cytoplasm of neutrophils and monocytes using ethanol-fixed leukocytes, and is therefore called *cytoplasmic ANCA* (c-ANCA) (Fig. 30.5). In contrast, MPO-ANCA produces a perinuclear staining pattern on neutrophils and monocytes (p-ANCA) (Fig. 30.6). A positive result on an IIF screening test for p-ANCA or c-ANCA should be confirmed using a specific ELISA employing MPO and PR3 as antigens.

The usefulness of ANCAs in monitoring disease activity in granulomatosis with polyangiitis has been controversial.^{18,19} They are useful in diagnosing ANCA-associated vasculitides but may not be that helpful in individual patients in predicting remission or relapse, and their measurement is not currently recommended for these reasons.

Complement

The most frequent clinical parameters used for judging complement activation are the protein levels of C3 and C4, although these values are of limited

Fig. 30.5 Cytoplasmic staining pattern of antineutrophil cytoplasmic antibodies.

Fig. 30.6 Perinuclear staining pattern of antineutrophil cytoplasmic antibodies.

use because they represent increased production during inflammation (acting as positive acute-phase reactants) and sometimes also consumption by immune complexes. Total hemolytic complement (CH50) is a functional assay used to measure the intactness and consumption of the entire classic pathway; however, it is rarely used nowadays because of its technical complexity. Decreased complement levels are useful in the setting of SLE nephritis, in which low levels are associated with persistent nephritis and normalization is associated with better outcomes. Hypocomplementemia is also a feature of preeclampsia/eclampsia, which is an important point to remember when caring for pregnant patients with SLE with and without antiphospholipid syndrome.

CONCLUSION

Laboratory tests are useful tools for diagnosis and for monitoring of adverse events related to medication use in some rheumatic conditions. Laboratory

results are secondary to clinical signs and symptoms and should not replace or detract from a thorough history and physical examination. As always, any test that will not change the diagnosis, prognosis, or treatment of a rheumatic condition probably should not be performed.

Synovial fluid analysis

■ ANTHONY J. FREEMONT ■ ENGY ABDELLATIF

- Normal synovial fluid is a hypocellular, avascular connective tissue.
- In disease, synovial fluid increases in volume and can be aspirated.
- Changes in synovial fluid cells, noncellular particles, and molecular biomarkers reflect the pathogenesis of the arthropathy.
- Synovial fluid microscopy, which identifies cells and particles, is a simple, cheap, and accurate test that yields information of diagnostic and prognostic significance.
- Cellular and molecular biomarkers of disease processes involving SF are increasingly being studied and may bring about a revolution in understanding and recognizing joint disease.

INTRODUCTION

Normal synovial fluid

Synovial fluid (SF) is a transudate of plasma supplemented with high-molecular-weight, saccharide-rich molecules such as hyaluronans and proteoglycan-4, as well as a host of “structural,” signaling, and effector molecules produced by synovial cells and chondrocytes.¹ Many of these molecules are involved in cartilage nutrition, joint homeostasis, and lubrication. The fluid is kept free of debris by macrophage-derived type A synoviocytes, and formation of SF is balanced by its removal via synovial lymphatics.

Unlike the lining of most body cavities, the surface of synovium consists of an incomplete cell layer with no intact basement membrane. The same is true of articular cartilage. The interfaces between the matrices of the two joint-lining tissues (synovium and cartilage) and joint fluid therefore have no regulatory cell layer to moderate fluid flux and the passage of cells and bioactive molecules. Thus, the chemical environment within the joint is relatively homogeneous, and changes in SF reflect changes within local tissues.

In a normal joint, SF contains few cells ($<200/\text{mm}^3$), mainly chondrocytes and synoviocytes, together with migratory defense cells (e.g., lymphocytes, macrophages). The nature and regulation of the chemical composition of SF are complex and poorly understood.

Synovial fluid in diseased joints

Variation in the volume and composition of SF reflects pathologic processes within the joint. Because of the anatomic relationships of the tissues in the joint, events such as inflammation and enzyme-mediated degradation are reflected by changes in the cellular and chemical composition of SF. Both the cellular and chemical changes have been widely studied to obtain a better understanding of disease processes and to identify aspects of diagnostic and prognostic utility.²

Synovial fluid microscopy

SF microscopy has been carried out as a diagnostic test for many years.³ Histologic and cytologic analysis of human tissues and body fluids is usually the exclusive realm of the pathologist. This is not the case with SF microanalysis, however, because it is possible to perform the test without complex technology. Consequently, it can be carried out close to the patient's bedside

by clinicians. Indeed, many clinicians have had a leading role in development of the science.^{4,5}

Detailed microscopic analysis of SF can yield significant information about the nature of joint diseases and their prognosis.² By comparison with other investigations (e.g., magnetic resonance imaging, serology), SF microscopy combines simplicity, economy, and clinical applicability across the whole spectrum of inflammatory and noninflammatory joint diseases.

SF microscopy gives diagnostic information with different levels of precision, from a single precise diagnosis at one end of the spectrum to simply distinguishing inflammatory from noninflammatory arthropathies at the other. This apparent lack of complete specificity should not be seen as detracting from the value of the test because the clinical question being considered by the rheumatologist may be answered by knowing whether the cause of the joint swelling is inflammatory (e.g., “Does my rheumatoid patient with long-standing disease, who now has a red, hot joint, have a rheumatoid flare or osteoarthritis?”). In the hands of experts, SF microscopy viewed “blindly” (i.e., without knowledge of any patient data) will give a precise diagnosis (e.g., a specific crystal arthritis, rheumatoid arthritis [RA], osteoarthritis [OA], torn meniscus, septic arthritis) in about 50% of cases. In a further 20% it allows relevant and clinically significant differential diagnoses to be made (e.g., 50% of patients with seronegative spondyloarthritis have a specific SF cytology that enables them to be distinguished with certainty from those with other forms of inflammatory arthropathy, including rheumatoid disease, even at initial evaluation,⁶ and in all but 2% to 3% of the remainder, SF microscopy can distinguish inflammatory from noninflammatory arthropathies). If these limitations of SF microscopy are properly considered and applied, the false-positive rate is very low (typically $<5\%$) and the false-negative rate almost zero.

At the same time it has to be acknowledged that access to dedicated laboratories with high throughput and specialized staff is, at best, patchy, and many rheumatologists and pathologists have to resort to SF analysis without expert support. Therefore, the next section of this chapter, which is based on the authors' experience in training young clinicians, technical staff, and nurses, will assist clinicians who find that they need to set up and use a small laboratory for analyzing SF specimens with microscopy to obtain reliable diagnoses.

THE BASIC APPROACH TO SYNOVIAL FLUID MICROSCOPY

SF analysis consists of four elements, with each requiring different types and complexity of equipment. The following approach will yield the maximum information for relatively little outlay and minimal time input. The equipment required is relatively simple: a microscope with polarizers and an interference plate, a hemocytometer chamber, and a cytocentrifuge.

It is important to recognize that SF should be examined unfixed, and consequently it should be treated with the same level of care as all other fresh body fluids. For health and safety reasons the samples should be handled in a biologic safety cabinet and, because fresh samples deteriorate rapidly even if kept refrigerated, should be examined within 24 hours of aspiration. Because SF from inflamed joints has a tendency to clot, it should also be anticoagulated. The best anticoagulant is lithium heparin.

The four elements of SF analysis are

- Visual inspection
- Nucleated cell count
- “Wet preparation”
- Cytocentrifuge preparation

Visual inspection

Synovial fluid should be examined for color and clarity.

Color

Normally, SF is pale yellow. With hemarthroses it will be red or orange and, with inflammatory arthropathies, cream or white. In septic arthritis it may be colored by bacterial chromogens.

Clarity

Normal SF is clear, but with increasing numbers of particles (e.g., crystals) or cells, it becomes cloudy.

Nucleated cell count

The nucleated cell count can be performed manually with a hemocytometer chamber or automatically with automated counters⁷ and even “dipsticks.”⁸ For convenience, the nucleated cell count of SF is expressed as cells/mm³ (directly equivalent to cells/ μ L). Normal SF contains fewer than 200 cells/mm³. In inflammatory joint disease the cell count is greater than 1000/mm³, and in noninflammatory arthropathies it is lower. Cell counts in excess of 50,000/mm³ are virtually restricted to four conditions: acute rheumatoid “flares” (including breakdown of disease control by anti-tumor necrosis factor) and septic, acute crystal, and reactive arthritis.

“Wet preparation”

SF aspirates often contain visible particles, usually fibrin clots or fragments of cartilage. In making the “wet preparation,” the specimen should be agitated and a small aliquot containing as many particles as possible placed on a microscope slide. It can then be gently squeezed flat beneath a cover slip and viewed unstained with a conventional microscope. For optimal results the condenser diaphragm should be closed to produce diffused light in which unstained cells and particles are seen clearly. This preparation is examined for one cell type, the ragocyte,⁹ for several different classes of crystals, and for other noncellular particulate material.

Classes of crystalline material

Several classes of crystalline material are found in joints,² and their detection is not as straightforward as sometimes thought¹⁰ (Fig. 31.1). Monosodium urate monohydrate (“urate”) crystals are needle shaped, 5 to 30 μ m in

length, and highly birefringent. They can be distinguished from other crystals by their properties in polarized light with an interference plate in the system. (For ease, it is useful to have on hand a microscope preparation made by smearing the contents of a tophus onto a slide because this known sample of urate crystals can then be used to standardize the optics of the microscope.) This system gives the microscope image a pink background against which urate crystals appear either yellow or blue, depending on the direction of their long axes. Other crystals, such as calcium pyrophosphate (“pyrophosphate”) crystals, are also yellow and blue, but the direction of the long axes of the yellow- and blue-appearing crystals is reversed. Urate crystals, especially when intraleukocytic, are diagnostic of gout.

Pyrophosphate crystals accumulate within joints with advancing age. In acute pseudogout, the crystals are associated with a high nucleated cell count. The presence of calcium pyrophosphate crystals in association with otherwise typical features of OA¹¹ characterizes hypertrophic OA.

Hydroxyapatite within SF indicates damage to calcified cartilage or sub-articular bone. Loss of cartilage sufficient to expose these structures is seen most commonly in OA¹¹ and RA. Hydroxyapatite crystalloids are too small and amorphous to be seen with the light microscope, but staining with alizarin red produces a birefringent red product that is easily visualized. A specific arthropathy, “Milwaukee shoulder” (and its equivalent in other joints), is associated with larger apatite microspheroids.¹²

Lipids enter SF from the blood in inflammatory joint disease, hemarthroses, and trauma to subsynovial fat. They are usually present either as droplets with a Maltese cross pattern (liquid spherical crystals) or as needle-shaped crystals within a droplet of neutral fat.

Following the intraarticular injection of depot corticosteroids, steroid crystalloids remain within the joint for up to 10 weeks and may mislead the unwary if their true nature is not recognized.

Other crystals are found within SF but are too numerous and rare to describe here. For further description see Freemont and Denton.²

Noncrystalline particles

Synovial joints are lined by cartilage and synovium, and some contain ligaments and fibrocartilage. In disease, small fragments of these structures may appear within SF. Most common are fragments of articular cartilage or, particularly in the knee, internal ligament and meniscal fibrocartilage.²

Articular cartilage has a silken sheen in polarized light. In OA, the most common disorder in which cartilage is found free in the joint, fragments typically show the crimp pattern characteristic of fibrillated cartilage or clusters of chondrocytes.

Fig. 31.1 A montage of common crystals. (a) “Urate” crystals viewed in polarized light with a quarter-wave plate. (b) Pyrophosphate crystals viewed in the same system. Note that pyrophosphate crystals appear duller and that the apparent color of the crystal is the opposite of the urate crystals when related to the long axis of the crystal. (c) A lipid droplet (arrow) containing a “beach ball” of needlelike crystals. (d) Hydroxyapatite crystals stained with alizarin red.

Fig. 31.2 Ragocyte (blue arrow) from a patient with rheumatoid arthritis showing the typical granules. An adjacent cell does not contain ragocyte granules (green arrow). This photograph was taken with a conventional microscope with the condenser iris almost fully closed (pseudophase). The preparation is unstained.

With the increase in arthroplastic surgery, increasing numbers of SF samples are being taken to identify wear, infection, and loosening. Many modern plastics used in prostheses (such as ultrahigh-density polyethylene), methylmethacrylate cement, and composites such as Dacron and carbon fiber mimic crystals if they fragment and can cause diagnostic problems. Metal debris from metal-based prostheses appear as tiny black particles that may exhibit refractivity. Though difficult to recognize, such particles may be important guides to imminent prosthetic failure.

In joints containing metal-on-metal prostheses in which the relatively newly recognized disorder (wrongly) called Aseptic lymphocyte-dominated vasculitis-associated lesion (ALVAL) is present, characteristic particles resembling worm casts are seen.^{12a}

Ragocytes

Ragocytes⁹ are cells of various lineage that are characterized by the presence of large, refractile cytoplasmic granules (Fig. 31.2). Ragocytes were first described in RA (hence the name), in which they have been shown to contain immune complexes. Some studies indicate that they may form *in vitro*.¹³ They are not restricted to RA but are a feature of all inflammatory arthropathies, so their diagnostic value is somewhat limited. However, with the exception of RA, septic arthritis, gout, and pseudogout, ragocytes rarely account for more than 50% of all nucleated cells. If a crystal arthropathy is excluded, ragocyte counts of 70% to 90% are very strongly suggestive of RA,¹⁴ and if above 90%, they are suggestive of septic arthritis.

Cytocentrifuge preparation

SF cytoanalysis can be conducted adequately only on monolayers made with a cytocentrifuge; smears are unacceptable preparations for this purpose. Optimal preparations are made by diluting the fluid to 400 cells/mm³ with isotonic saline and staining with a Giemsa stain. The one exception is when septic arthritis is suspected, in which case the greatest likelihood of identifying organisms is afforded by diluting the fluid to 1200 cells/mm³ and staining with Gram stain.

Many different cell types are found within SF and reflect differences in the pathogenic mechanisms of joint disease. Although epitope-defined subclasses of inflammatory cells are being characterized by immunocytochemistry and have been found to have disease-specific distributions,¹⁵ this has yet to be fully exploited diagnostically, in part because of problems in performing immunocytochemistry on cytocentrifuge preparations. Therefore, cell recognition in SF preparations is currently based largely on morphologic criteria.

In general, polymorphonuclear leukocytes dominate the cytologic picture in inflammatory arthropathies. Septic arthritis is the only disorder in which both ragocytes and neutrophils account for more than 95% of the nucleated cells.

In noninflammatory arthropathies, lymphocytes, macrophages, and synovocytes are the most commonly encountered cells.

In a patient with RA, SF in which more than 80% of the nucleated cells are small lymphocytes is indicative of less destructive and more slowly

Fig. 31.3 Cytophagocytic mononuclear cell (blue arrow) in which an apoptotic polymorph has been phagocytosed by a macrophage. An apoptotic polymorph is adjacent to it (green arrow).

progressive local disease.¹⁶ If lymphocytes account for more than 70% of the nucleated cells and LE cells are present in the fluid, a diagnosis of systemic lupus erythematosus has to be seriously considered.

Macrophages are the predominant cell (>80% of nucleated cells) in viral arthritis, Milwaukee shoulder, some forms of chronic pyrophosphate arthritis, pigmented villonodular synovitis, and prosthetic debris-induced arthropathy. The presence of macrophages that have phagocytosed apoptotic polymorphonuclear leukocytes (cytophagocytic mononuclear [CPM] cells) (Fig. 31.3) is diagnostic of the seronegative spondyloarthritis.¹⁷

In RA, extensive apoptosis occurs in the absence of CPM cell formation, a feature of such universal occurrence that it can be used diagnostically.

Mast cells, though found in most arthropathies, are seen most commonly in the seronegative spondyloarthritis and in traumatic arthritis.¹⁷

THE PLACE OF SYNOVIAL FLUID MICROSCOPY IN DIAGNOSIS

Synovial biopsy is the investigation of choice for diseases with specific synovial appearances,¹⁸ such as granulomatous inflammation or pigmented villonodular synovitis. However, even experienced histopathologists can sometimes find it difficult to distinguish inflammatory from noninflammatory arthropathies, and very few features in a synovial biopsy specimen will allow a specific diagnosis to be made from within one of these two groups.¹⁹

On this background, SF microscopy is of greatest value for the following:

- Differentiation between inflammatory and noninflammatory arthropathies
- Identification of specific inflammatory and noninflammatory arthropathies even before the full clinical syndrome develops
- Diagnosis of unexplained monoarthritis and oligoarthritis
- Rapid diagnosis of joint disease, particularly in suspected cases of septic arthritis, in which the prognosis is inversely related to the delay in diagnosis

Figures 31.4 to 31.6 present simple algorithms showing how the information obtained from the examinations outlined can feed into the diagnostic process.

DIAGNOSIS OF INTRAARTICULAR INFECTION

Infection in joints is a common cause of joint effusion, a major clinical concern and very difficult to diagnose. SF microscopy has some part to play in the diagnosis of nonseptic infective arthritis, but it is in the setting of septic arthritis that the precision and rapid turnaround times of SF microscopy have their most substantial role, particularly in patients with the following:

- A single red hot joint of sudden onset
- A joint replacement with persistent effusion or pain
- “Immunosuppression” and an effusion (e.g., rheumatoid disease, infection with human immunodeficiency virus [HIV])

Fig. 31.4 Algorithm for low cell count fluid. OA, osteoarthritis.

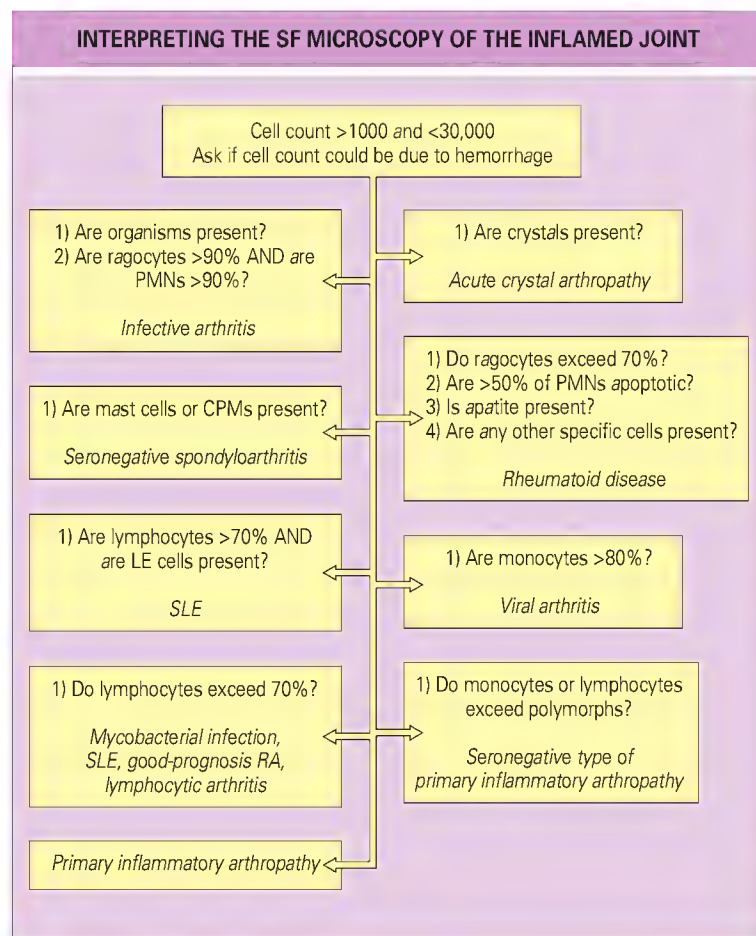

Fig. 31.5 Algorithm for synovial fluid microscopy of the inflamed joint. CPMs, cytophagocytic mononuclear cells; PMNs, polymorphonuclear leukocytes; RA, rheumatoid arthritis; SF, synovial fluid; SLE, systemic lupus erythematosus.

Septic arthritis

Not all bacterial infections lead to septic arthritis.²⁰ By far the most common (75% to 80%) causes of septic arthritis are the gram-positive cocci *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*, the remainder being largely caused by the gram-negative coccus *Neisseria gonorrhoeae* and the gram-negative bacilli *Pseudomonas aeruginosa* and *Escherichia coli*, the latter being more common with immunosuppressed states. In children younger than 2 years, *Haemophilus influenzae*, *S. aureus*, and group A streptococci have been the most common, but the incidence of *H. influenzae*

Fig. 31.6 Algorithm for very high cell count fluid. CPMs, cytophagocytic mononuclear cells.

septic arthritis has fallen dramatically since the introduction of type b *H. influenzae* vaccination.

In septic arthritis, careful microscopic examination of SF allows microorganisms to be identified but not classified beyond gram-positive or gram-negative cocci or bacilli. The greatest problems in diagnosing septic arthritis are caused by the relative paucity of organisms in most cases, recognition of gram-negative organisms, and identification of gram-positive cocci rendered gram negative by incomplete antibiotic therapy. In these settings nothing can compensate for patience and experience. Microbiologic culture is also important, but there is little benefit in sending all SF specimens for culture, and in this respect SF microscopy can be used as a rapid screening test for organisms and to exclude other causes of an acutely inflamed single joint, such as a crystal arthropathy or reactive arthritis.

Even in the absence of identifiable organisms, SF microscopy can be very useful in identifying patients with a high probability of having infection. Finding a ragocyte count higher than 95%, total nucleated cells, a nucleated cell count higher than 20,000/mm³, or polymorphonuclear leukocytes accounting for greater than 90% of the nucleated cells should trigger examination of Gram-stained cytocentrifuge preparations or lead to a recommendation for SF and blood samples to be sent for culture (or both).

The reliance on quantitative cytology to make the diagnosis of bacterial infective arthritis in the absence of identification of organisms has been taken further in joints with prostheses following a paper from the Mayo Clinic. It was shown that a nucleated cell count of greater than 1700/mm³ has a sensitivity of 94% and a specificity of 88% in diagnosing prosthetic joint infection in the knee and that a differential count of greater than 65% neutrophils has a sensitivity of 97% and a specificity of 98%²¹; consequently, this has become an area of great interest.²²

Other increasingly common bacterial joint pathogens (e.g., *Neisseria*, *Salmonella*, *Mycobacteria* [including atypical forms]) that do not cause septic arthritis can be identified in SF both by culture and by direct microscopic examination of appropriately stained cytologic preparations.

Nonbacterial infections

Fungal infections are diagnosed by the same approaches suggested for bacteria. By contrast, viral infections are more difficult to diagnose, although an interest in the arthritides associated with HIV infection has shown the diagnostic importance of some features that are seen in no other disorder, such as the coexistence of septic and reactive arthritis in the same joint.

Future techniques

New techniques such as proteomics or polymerase chain reaction using organism-specific primers or amplifying widely expressed bacterial nucleic acid sequences (e.g., 16S ribosomal component) may expand the diagnostic armamentarium in the future.^{23,24}

CHEMICAL CHANGES IN SYNOVIAL FLUID IN DISEASE

The biochemical changes in SF in disease may reflect abnormalities in blood or result from the production of an excess of normal products or the presence of abnormal products in the synovium, cartilage, or fluid itself. In general, because the products of normal or abnormal joint metabolism will be in dynamic equilibrium with serum and be dependent on a complex set of variables such as the hydrostatic and osmotic gradients across the joint, isolated single estimations of a product are not easy to interpret. This is compounded by a lack of availability of normal SF for comparison with disease samples.

Thirty years ago, when biochemical analysis of SF was first studied in earnest, small molecules (e.g., glucose), ions, and pH were the focus of research but, for the reasons given earlier, never gained favor diagnostically. Since then, there have been phases of interest in measuring drug levels and antibodies, which again proved to be of limited value diagnostically.

However, burgeoning recent interest in the discovery and analysis of novel molecular biomarkers (molecules indicative of specific pathologic processes)²⁵ may ultimately help pinpoint specific disease processes within a joint, in much the same way as the cellular and particulate biomarkers discussed earlier.

To date, the range of biomarkers that have been investigated is based on studies of specific molecules predicted to be important from the current understanding of molecular drivers of disease processes. However, many of these findings lack consistency or specificity (or both), particularly as markers of the presence or activity of disease in individuals or specific joints.

There can be little doubt that the advent of widely available proteomics and metabolomics, coupled with robust bioinformatics, will result in a huge increase in the number of biomarkers and peptide/protein “fingerprinting” of disease processes. There is already some evidence of the success of this type of approach when applied to SF, but the opportunities that these technologies open up could herald a revolution in the identification of disease processes and subtypes, a reclassification of joint disease, and advances in diagnosis and prognostication.

Minimally invasive procedures

■ DANIELLE M. GERLAG ■ PAUL P. TAK

- Various minimally invasive procedures ranging from arthrocentesis to synovial biopsy can be used in daily rheumatology practice to determine the diagnosis or to monitor the response to treatment.
- Analysis of joint fluid can distinguish between an inflammatory and noninflammatory cause of arthritis and is especially helpful in the case of monoarthritis, when septic arthritis or crystal-induced arthritis is suspected.
- In the diagnostic workup of patients with rheumatologic disease, especially when systemic disease is suspected, histologic samples can be of great additional value.
- Abdominal fat pad fine-needle aspiration is a relatively noninvasive, simple, and safe technique with excellent specificity and positive predictive value in establishing the diagnosis of amyloidosis.
- When inflammatory myositis syndromes such as polymyositis, dermatomyositis, and inclusion body myositis need to be distinguished from other myopathic syndromes, a histologic sample of the involved muscle or muscles often leads to a definite diagnosis.
- Minor salivary gland biopsy of the sublabial glands is a simple technique that can be performed in an outpatient setting when histologic confirmation of suspected Sjögren syndrome, sarcoidosis, and other infiltrative processes is necessary.
- Synovial tissue biopsy samples can be taken safely on an outpatient basis with blind needle or arthroscopic techniques. Analysis of synovial tissue can be performed for diagnostic reasons in selected cases, to study pathogenetic processes in various types of arthritis, and to evaluate the response to (experimental) treatment in a research setting.

INTRODUCTION

Several minimally invasive procedures can be performed in daily rheumatology practice to determine the diagnosis or monitor the response to treatment. Such techniques include arthrocentesis and biopsy of the skin, muscle and fascia, salivary gland, abdominal fat pad, and synovium. This chapter reviews and describes the processes to be followed for each of these techniques and discusses the indications for and potential complications of the procedures.

ARTHROCENTESIS

Since its introduction in 1951 by Hollander, aspiration of fluid from a joint cavity is performed on a routine basis by rheumatologists for both diagnostic and treatment reasons. Analysis of joint fluid can distinguish between an inflammatory and noninflammatory cause of arthritis and is especially helpful in the case of monoarthritis, when septic arthritis or crystal-induced arthritis is suspected. In addition, arthrocentesis can be used therapeutically when accumulation of fluid in a joint causes painful distention of the joint capsule. Intraarticular therapy with corticosteroids or other preparations can be of adjunctive value in the treatment of several types of arthritis.

Physical landmarks and a thumbnail, ballpoint pen, or marker can be used to carefully determine and indicate the site of puncture. In some cases, such as the hip and sacroiliac joint or when the synovial fluid is loculated, imaging techniques are necessary to ensure correct position of the needle

in the joint cavity. Although the risk of contaminating the joint through the arthrocentesis itself is extremely low, aseptic measures to prevent this complication are necessary. After determining the aspiration or injection site, the skin over this area should be disinfected, which can be done with iodine solution or an alcohol-based disinfectant. It is important to allow the disinfectant fluid to dry. The use of gloves is generally advisable to protect oneself from possibly infected body fluids, but routine use of sterile gloves is unnecessary. When a relatively small joint is to be punctured, use of a local anesthetic—such as a 1% or 2% lidocaine solution without epinephrine—to anesthetize the skin, subcutaneous tissue, and joint capsule can minimize discomfort during the procedure. When rapid insertion of the needle into a joint is possible, use of a local anesthetic is not necessary, or it can be mixed with the corticosteroid or other agent to be injected. The use of local anesthetics can also yield diagnostic information about the exact location and nature of the pain. Most aspirations can be performed with a 21-gauge needle, but a 19-gauge needle can be chosen when large and viscous effusions are being aspirated. Smaller (23-gauge) needles can be used for small joints such as the metacarpophalangeal or interphalangeal joints. If the needle is inserted into the joint correctly but no fluid can be aspirated, the needle might be clogged with fibrin or so-called “rice bodies.” Irrigation of the joint with isotonic saline or some lidocaine can sometimes result in fluid that contains enough crystals or bacteria to establish the diagnosis. If a therapeutic agent is to be injected after the aspiration has been completed, the syringe can be removed and replaced by the syringe with the medication. After ensuring that the needle is still in the joint cavity, the medication can be injected.

Complications of arthrocentesis are extremely rare but include idiopathic infection and bleeding.

BIOPSIES

In the diagnostic workup of patients with rheumatologic disease, histologic samples can be of great additional value. Especially when systemic disease is suspected, combining the clinical symptoms with the characteristic features of the affected tissue gathered with minimally invasive techniques can lead to the correct diagnosis.

Skin and subcutaneous tissue

Technique

Although many skin lesions may directly suggest a diagnosis when combined with the clinical information and the aspect and specific location of the lesion, histologic evaluation of skin abnormalities can help differentiate between different syndromes. Skin biopsy specimens are best taken from a recently developed lesion and should contain normal-appearing skin alongside the edge of the lesion.¹ Using a disposable punch biopsy tool 3 to 6 mm in diameter, diagnosis of dermal and subdermal abnormalities can be determined. After anesthetizing the skin around the biopsy site with 1% to 2% lidocaine, a small cylinder of tissue is removed with a twisting movement of the punch. After achieving hemostasis, the wound can be closed primarily or be left to heal by secondary intention. Both procedures will lead to formation of a small scar. Complications of the procedure are rare and include bleeding, especially when anticoagulants or nonsteroidal antiinflammatory drugs are used, and infection.

If vasculitis or panniculitis is suspected, excision biopsy via scalpel and forceps is more reliable in revealing the diagnosis because a larger amount of tissue that contains panniculus can be examined and thus provide a greater chance of finding abnormalities.¹ A larger amount of tissue also allows additional studies such as immunohistochemistry,

Fig. 32.1 (a) Psoriasis. The epidermis shows regular elongation of the epidermal rete ridges. The cornified layer shows confluent parakeratosis. A superficial perivascular lymphocytic infiltrate is present. (b) Psoriasis detail showing exocytosis of neutrophils.

Fig. 32.2 (a) Chronic discoid lupus erythematosus (CDLE). The epidermis shows hyperkeratosis, follicular plugging, atrophy, and basal layer vacuolization. A dense perivascular lymphoid infiltrate is present. (b) CDLE detail.

immunofluorescence, and electron microscopy. For cosmetic reasons, the line of incision should follow the natural lines of the skin.

Skin biopsy for specific rheumatologic disorders

In *psoriasis*, the epidermis is characterized by thickening of the viable cell layers (acanthosis), marked hyperkeratosis (thickening of the cornified layer), loss of the granular layer, and parakeratosis (nuclei in the stratum corneum). In addition, the contorted dermal blood vessels are increased in number and size and extend up to the epidermis. Furthermore, leukocyte infiltration is found in the dermis and epidermis, where some leukocytes form Munro microabscesses underneath the stratum corneum (Fig. 32.1a and b). Immunostaining with anti-CD3 antibodies (a T-lymphocyte marker) has shown that these infiltrates contain many T cells.²

In *lupus erythematosus* (LE), the lesions can be diverse and biopsy can help distinguish between different lesions. Discoid skin lesions show characteristic features: follicular plugs, atrophy, scale, telangiectases, and erythema (“paste” features) (Fig. 32.2a and b).

Direct immunofluorescence (DIF) techniques can be helpful in diagnosing various subsets of LE and vasculitis because the site, morphology, and frequency of deposition vary among these subsets.^{3,4} DIF requires fresh tissue, which can potentially be substituted by immunohistochemical analysis of paraffin-embedded tissue. This latter technique can be used as an adjunct in the assessment of certain inflammatory skin diseases, including vasculopathic conditions and collagen vascular disease.⁵

In *discoid lupus*, immune deposits of mainly IgG and IgM are found in various patterns along the dermoepidermal junction in about 60% to 94% of biopsy samples of lesional skin.⁶ Previous treatment, sun exposure, and duration of the lesion may influence the frequency of positive immunofluorescence. Therefore, the most appropriate biopsy site is an older, untreated lesion that has not been exposed to the sun.

The skin lesions in *systemic LE* may have immune deposits in various sites. Granular deposits of immunoglobulins and complement proteins are found at the dermal-epidermal junction (lupus band).⁷ Other deposition sites include the superficial dermal blood vessel walls, cytotoid bodies in the papillary dermis, and nuclei of the epidermal keratinocytes.⁸

In *scleroderma*, mononuclear infiltrates, mainly consisting of T cells located around blood vessels, and increased collagen, synthesized by activated fibroblasts and leading to tissue fibrosis, can be seen in early lesions.⁹ These findings can be found in localized processes, such as morphea.

Various types of *vasculitis* (leukocytoclastic, eosinophilic, Henoch-Schönlein, polyarteritis nodosa) can be distinguished by histologic analysis of the skin or a subcutaneous lesion in which representative vessels are included. The tissue sample should be of adequate size. When taken from an active lesion, the chance of a false-negative result will be less than when taken from normal skin (Fig. 32.3a and b). Additional immunofluorescent techniques will classically show IgA deposition in *Henoch-Schönlein purpura* (Fig. 32.4), but this can also be seen with other IgA-associated forms of vasculitis such as lymphocytic vasculopathy.¹⁰

Rheumatoid nodules are characterized by palisading fibroblasts surrounding a central area of necrosis. These fibroblasts are in turn surrounded by chronic inflammatory cells, mainly lymphocytes. Various proinflammatory cytokines, components of the complement system, and rheumatoid factor can be found in these granulomas.^{11,12}

Abdominal fat pad fine-needle aspiration

Abdominal fat pad fine-needle aspiration is a relatively noninvasive, simple, and safe technique for establishing the diagnosis of amyloidosis.^{13,14} This technique has excellent specificity and positive predictive value. Using an 18- to 23-gauge needle, aspiration is performed two to five times on different locations from the xiphoid process to the symphysis. The aspirated material is gently distributed on a glass slide and allowed to dry.¹⁵ When stained with Congo red, a specific apple-green birefringence caused by binding to the amyloid can be seen under polarized light. The amyloid deposits are distributed mainly perivascularly and range from massive to subtle (Fig. 32.5). Fluorescent microscopy can improve the detection of amyloid in fat pad smears.¹⁶ Novel proteomic strategies based on mass spectrometry have been proposed to identify the protein constituents of the deposits. Multidimensional Protein Identification Technology is an automated, high-throughput proteomic approach that allows the identification of hundreds of proteins

Fig. 32.3 (a and b) Leukocytoclastic vasculitis. Vascular damage with a perivascular neutrophilic infiltrate, nuclear debris, and extravasation of erythrocytes is apparent.

Fig. 32.5 Amyloidosis. Amyloid deposits observed under polarized light show a greenish birefringence of Congo red-stained amyloid fibrils.

in complex samples.¹⁷ The sensitivity and specificity of the fine-needle aspiration technique range from 55% to 75% and up to 92% to 100%, respectively.^{14,18} No complications of this technique have been reported. Variants of the technique include Tru-Cut needle biopsy or excision biopsy. Other possible biopsy sites to confirm amyloidosis are the rectal mucosa, labial salivary gland, and compromised organs (kidney, liver, and endomyocardium). The latter sites should be reserved for patients in whom the aforementioned techniques have failed to establish the diagnosis.

Biopsy of the temporal artery

The “gold standard” for the diagnosis of giant cell arteritis is biopsy of the temporal artery. It should be performed as soon as the diagnosis is suspected, but without delaying treatment. This procedure is usually performed by surgeons.

The suggested sample size is 2.5 to 5 cm because the inflammation is discontinuous, which causes skip lesions (reported in about 10% of cases).¹⁹ Biopsy of the contralateral side is suggested if findings on the first biopsy sample are negative. The sensitivity of a positive biopsy result was reported to not be significantly decreased after 2 weeks of steroid therapy,²⁰ and several case reports have suggested the persistence of histologic abnormalities even after months of treatment.²¹

A meta-analysis of the sensitivity and specificity of clinical signs and symptoms showed various clinical features, such as jaw claudication, diplopia, and the erythrocyte sedimentation rate, to be predictive of a high or low probability of a positive temporal artery biopsy.²² Several other variables influence the reported 3% to 10% incidence of false-negative results: the length and number of biopsy specimens taken, the presence of skip lesions, pathologic sectioning techniques, and the duration of treatment before biopsy.²³ Using bayesian analysis, the sensitivity of a single temporal artery biopsy specimen was calculated to be 89.1% (95% confidence interval, 81.8% to 91.7%).²⁴ The use of imaging techniques, such as B-flow ultrasound and high-resolution magnetic resonance imaging (MRI), may perhaps be of help in defining the arterial segment for biopsy to decrease sampling error.²⁵

Mononuclear infiltrates penetrating all layers of the arterial wall and causing panarteritis can be seen along with activated T cells and macrophages arranged in granulomas.²⁶ In 50% of cases, multinucleated giant cells are found grouped along the fragmented internal elastic lamina (Fig. 32.6a and b). Temporal artery biopsy is a safe procedure with a low complication rate. Complications include postoperative hematoma, wound infection or dehiscence, and facial nerve damage.²⁷

Muscle/fascia

When inflammatory myositis syndromes such as polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM) need to be distinguished from other myopathic syndromes, a histologic sample of the involved muscle or muscles often leads to a definite diagnosis. Furthermore, atypical inflammatory myopathies such as pyomyositis, parasitic diseases, and granulomatous myositis in sarcoidosis can be identified.²⁸

Site selection is crucial when performing a muscle biopsy. A muscle biopsy specimen should be taken from an involved muscle identified by physical examination, but from not a fully atrophic or severely weakened one. Also, care should be taken to not obtain samples from a muscle that was injected or has recently been evaluated by electromyography (EMG) because of the chance for focal traumatic myositis. Taking a muscle sample from the side contralateral to the one found to be abnormal on EMG may increase the yield of finding diagnostic abnormalities. The quadriceps or deltoid muscles are involved in most myopathies and are the easiest to access.

Furthermore, the use of MRI to identify affected areas that show increased T2 signal may also help reduce sampling error. The value of fat-suppressive (short tau inversion recovery [STIR]) image signal intensity was studied in 40 patients with idiopathic inflammatory myopathies and correlated significantly with clinical activity and the presence of inflammation on muscle biopsy samples.²⁹ In this study, signal intensity scores were found to be more sensitive in detecting clinical disease activity than was the presence of pathologic changes on muscle biopsy specimens (89% versus 66%).

Fig. 32.6 (a) Arteritis temporalis. Low magnification shows partial destruction of the wall by an inflammatory infiltrate containing multinucleated giant cells, which led to fragmentation of the internal elastic lamina and extreme narrowing of the lumen (hematoxylin-eosin). (b) Arteritis temporalis (detail, elastic–Van Gieson stain).

Open biopsy has several advantages because a larger tissue sample can be obtained under direct vision. This reduces the chance of sampling error and allows multiple diagnostic tests.³⁰ Despite these advantages, 25% to 30% of patients with myositis still have negative biopsy results.³¹ With suspected inherited metabolic myopathies, for which multiple quantitative assays need to be performed, open biopsy is recommended.³² This technique, however, requires the assistance of a surgeon and the use of local or regional anesthetics, it can be done only on superficial muscles, it is not suitable for serial biopsy assessment, and it leads to scar formation. Alternatively, the various percutaneous needle muscle biopsy techniques that have been developed are more cost-effective, are more convenient for daily practice, and yield adequate tissue samples for histology, histochemistry, and electron microscopy.³⁰ Some procedures require a skin incision, such as when a disposable Tru-Cut biopsy needle, a suction-assisted reusable device with a side-cutting window and inner cutting cylinder (University College Hospital instrument) (Fig. 32.7), or a sharp-jawed surgical instrument (conchotome) is used.³³

When using the suction-assisted, spring-loaded needles (Bard Biopsy-Cut instrument) originally described by Coté and colleagues,³⁴ more samples can be taken from the same or more than one muscle, which may improve sensitivity.^{31,32,34,35} Additional advantages include the ability to perform this method at the patient's bedside, the fact that no skin incision is required, and the possibility of taking serial biopsy specimens to evaluate treatment. Complications from this technique, such as small hematomas, are rare.

Although the diagnostic value of the specific histopathologic features found in muscle biopsy samples from patients with inflammatory syndromes is somewhat controversial,³⁶⁻³⁸ the combination of clinical information and histologic analysis may result in different therapeutic options and prediction of prognosis.

In inflammatory myopathies, myofiber degeneration, regeneration, and an inflammatory infiltrate consisting of mononuclear cells are usually found. In PM, invasion of cytotoxic T cells into nonnecrotic myofibers can be seen. Typical histologic changes in DM include perimysial perivascular inflammation with B and T cells, capillary involvement, and atrophy of the fibers secondary to ischemia. In IBM, chronic myopathic features, endomysial lymphocytic inflammation, and rimmed vacuoles are present. Filamentous inclusions may be seen on ultrastructural studies. Immunohistochemistry can be of help in determining the diagnosis. With the increasing availability of various antibodies to proteins, both paraffin-embedded sections and (sequential) cryosections can be used for immunohistochemical analysis of the inflammatory infiltrates.³⁹ In most metabolic myopathies, however, immunohistochemistry is not advantageous.

Salivary gland

The main indication for salivary gland biopsy is histologic confirmation of suspected Sjögren syndrome, sarcoidosis, and other infiltrative processes such as amyloidosis and hemochromatosis. Various techniques have been described, each with advantages and disadvantages.

Minor salivary gland biopsy of the sublabial glands is one of the most widely used procedures. It is a simple technique that can be performed in an outpatient setting. The patient is seated or lying with the upper half of

Fig. 32.7 Percutaneous muscle biopsy using a suction-assisted instrument.

Fig. 32.8 (a) Lip biopsy: incision of the lower lip. (b) Biopsy specimen.

the body upright. The lower lip is everted and the mucosa inspected. The biopsy site should contain normal-appearing mucosa and enlarged labial glands (1- to 2-mm firm nodules), as determined by palpation. The area is infiltrated with local anesthetic (e.g., 2% lidocaine with or without epinephrine/adrenaline), and a small superficial 0.1- to 1-cm incision is made (Fig. 32.8a and b). The salivary glands (preferably 5 to 10) are bluntly dissected by grasping them carefully at the base with forceps and applying gentle upward traction.⁴⁰ Light pressure can help bulge the gland from the incision wound.⁴¹ Care should be taken to not damage the sensory nerves, which can easily be distinguished during the procedure. The incision can be closed with dissolvable sutures, but it may be allowed to heal spontaneously. Possible complications include bleeding from an incision that is too deep, damage to the sensory nerve leading to permanent hypoesthesia of the lower lip, and burning of the mouth after the procedure because of drinking hot beverages while still anesthetized.

The glands are fixed in formalin, embedded in paraffin, and stained with hematoxylin-eosin. For evaluation of the diagnosis of Sjögren syndrome, the inflammatory infiltrate is scored and graded according to the method of Greenspan and Daniels,⁴² which is based on the number of inflammatory cells (foci) within the biopsy section. These foci are usually found perivascularly or periductally, adjacent to the acini of the glands. Classically, a single tissue section is taken to evaluate the infiltrate, but despite standardization of the methodology of sampling, processing, and examining the specimens, reproducibility of histologic scores remains low. To increase the diagnostic accuracy of this test, multilevel sectioning (three different levels at least 200 μ m apart) and use of a cumulative focus score have been recommended.^{43,44} Furthermore, the use of immunohistochemical techniques to quantify the IgA- and IgG-containing plasma cells in the biopsy sample results in higher sensitivity and specificity of the test.⁴⁵

Biopsy procedures on other salivary glands, such as the parotid gland, have also been described. Parotid biopsy for diagnosis of adult and pediatric Sjögren syndrome is safe and accurate.^{46,47} Comparison of parotid and minor salivary gland biopsy shows little added value of the former, especially if other diagnoses such as lymphoma or sarcoidosis are suspected.^{48,49}

Synovium

Because synovial tissue is easily accessible, biopsy samples can be taken safely with blind needle or arthroscopic techniques. Subsequent analysis of synovial tissue can be used for diagnostic reasons in selected cases⁵⁰⁻⁵³ to study the pathogenetic processes in various types of arthritis and evaluate the response to (experimental) treatment in a research setting.^{54,55}

Blind, or closed, needle biopsy has been performed successfully with the Parker-Pearson needle, which is a simplified 14-gauge biopsy needle that does not require a skin incision (Fig. 32.9a).⁵⁶ This technique is safe, well tolerated, technically easy, and inexpensive. After using standard aseptic technique and anesthetizing the skin, subcutaneous tissue, and joint capsule with 1% or 2% lidocaine (see also earlier discussion on arthrocentesis), the trocar is inserted into the joint and the biopsy needle is introduced into the trocar (see Fig. 32.9b and c). Applying suction to a Luer-Lok syringe attached to the biopsy needle helps in obtaining the specimen (see Fig. 32.9d). When the angle of the needle is altered, multiple biopsy specimens can be obtained. Taking six or more biopsy samples from multiple locations reduces the chance of sampling error and leads to a variability of less than 10%.⁵⁷ In patients with minimal or no clinical evidence of inflammation or effusion, the use of 10 to 20 mL of isotonic saline to fill the joint cavity before introducing the trocar may be helpful. Most investigators use this

technique to perform biopsy on the knee joint, but biopsy of other joints such as the ankle, wrist, elbow, and shoulder has also been described. Smaller joints can be approached with a modified short needle.⁵⁸ In most cases this technique yields adequate tissue samples, with signs of inflammation generally being similar to those in samples taken under direct vision via an arthroscopic technique.⁵⁹ It can fail, however, when the joints are not swollen. In a series of more than 800 samples, no complications (such as infection or hemarthrosis) were seen.⁵² Several modifications of this technique have been described, such as use of the Tru-Cut needle for a variety of soft tissue biopsies. This is an inexpensive, disposable item that can retrieve synovial tissue through an action similar to that described earlier.

Arthroscopic biopsy

Because blind needle biopsy has limitations (e.g., restriction to larger joints, potential sampling error because of the blind character of the procedure, and difficulty obtaining adequate tissue when the joint is not clinically inflamed), it may be advantageous to obtain synovial tissue with a small-bore arthroscope (Fig. 32.10). Knee arthroscopy can be performed by introducing a small-bore arthroscope or needle arthroscope ranging in size from 4.5 to 2.7 mm into an infrapatellar skin portal, which is created after disinfecting and anesthetizing the skin, subcutis, and knee joint (Fig. 32.11a). A suprapatellar second skin portal is created for the grasping forceps. This technique allows macroscopic examination of the synovial tissue and biopsy of different sites in the joint under direct vision. It can also be used when biopsy samples of an ankle joint are taken through a medial and lateral malleolar portal. A small-bore, 1.9-mm arthroscope can be used for a smaller joint, such as the metacarpophalangeal joint or the wrist through radial and ulnar skin portals (see Fig. 32.11b and c). Inflammatory markers are generally comparable in biopsy samples taken from the knee and a smaller joint such as the wrist.⁶⁰

This technique, performed in an outpatient setting under local or regional anesthesia, is being performed by an increasing number of rheumatologists and is well tolerated by patients. Minimal pain and discomfort during the procedure and minor complications such as vasovagal reactions and temporary swelling of the joint are reported by 35% to 36% and 5% to 10% of patients, respectively.⁶¹ The total complication rate mentioned in a recent survey was 15.1 per 1000 arthroscopies, which is comparable to rates mentioned in the orthopedic literature.⁶² The complications consisted of joint infection (0.1%), deep vein thrombosis (0.2%), and hemarthrosis (0.9%). The amount of irrigation fluid used has been found to correlate with the wound infection and total complication rate, possibly a reflection of the duration of the procedure.

ARTHROSCOPIC JOINT LAVAGE

Joint lavage can be considered for different conditions, such as persistent arthritis after needle aspiration, osteoarthritis, and septic arthritis. The therapeutic effect of joint lavage is attributed to the removal of proinflammatory cells and their destructive enzymes, as well as cartilage degradation products. Although various uncontrolled, retrospective studies have reported a beneficial therapeutic effect of joint lavage for osteoarthritis of the knee joint, a randomized, placebo-controlled trial did not show superiority of this procedure over placebo.⁶³ Moreover, joint lavage alone or combined with infiltration of corticosteroid was similarly effective for symptomatic management of osteoarthritis of the knee; the effects persisted for 3 to 12 months.^{64,65}

CLOSED BIOPSY OF KNEE SYNOVIUM

Fig. 32.9 (a) Parker-Pearson needle. (b) Procedure for blind needle biopsy of the knee. (c) Schematic drawing of a blind needle biopsy procedure of the knee. (d) Synovial tissue specimen.

Fig. 32.10 Needle arthroscope.

For inflammatory conditions such as rheumatoid arthritis, the efficacy of joint lavage is still somewhat controversial. Retrospective analysis of the therapeutic effect of needle aspiration and joint lavage in 50 patients revealed that arthroscopic lavage had a superior effect.⁶⁶ This seems to be dependent on the volume of physiologic fluid used during the procedure, with 5 to 10 L giving the best results.^{67,68} Furthermore, the effects of joint lavage are more beneficial in patients with milder disease.

ULTRASOUND-GUIDED SYNOVIAL BIOPSY

Another method increasingly being used to obtain synovial biopsy samples is the recently developed office-based, mini-invasive, ultrasound-guided technique.⁶⁹ This procedure uses ultrasound guidance as an aid to acquire synovial tissue percutaneously by means of a portal and a rigid forceps technique.⁷⁰ This approach combines the advantages of being minimally invasive and being able to sample inflamed synovial tissue under indirect visual inspection. When a multifrequency linear transducer is used, effusion and synovitis can be identified. The sensitivity of this technique can be enhanced by applying power Doppler techniques.⁷¹ Under standard sterile conditions and after infiltrating the skin and subcutaneous tissue with local anesthetic, a 14-gauge needle can be inserted into the designated area under ultrasound guidance. After creating a portal by means of a flexible wire followed by a percutaneous sheath, synovial samples can be acquired with rigid forceps.^{69,70}

ACKNOWLEDGEMENT

The authors would like to acknowledge Dr. L. Schot and Prof. Dr. S. Florquin for the illustrations of the lip biopsy and histology of the skin.

Skin in rheumatic disease

■ MARKUS BÖHM ■ THOMAS A. LUGER

- Skin is involved frequently in rheumatic diseases.
- Skin manifestations can be hallmark features in some rheumatic diseases, especially lupus erythematosus, dermatomyositis, and systemic sclerosis.
- Skin changes in rheumatic diseases are specific when characterized by a distinct clinical and histopathologic picture.
- Nonspecific skin changes occur in a variety of diseases but not exclusively in a distinct rheumatic disorder.
- Skin involvement can alert the clinician to a different course, therapeutic approach, and prognostic outcome in a patient with rheumatic disease.

INTRODUCTION

Skin changes occur in a variety of rheumatic diseases and are of particular relevance for clinicians dealing with such diseases for several reasons. First, skin can be the initial site of involvement in a rheumatic disease, thereby providing the physician with important clues to the correct diagnosis. Second, skin involvement in a rheumatic disease may serve as an easy-to-access indicator of both systemic involvement and prognostic outcome of the disorder. Third, because of the important psychosocial function of the skin, physicians need to be fully aware of the impact that chronic and often disfiguring skin changes may have on the quality of life of a patient with rheumatic disease. Fourth, skin changes may be induced *de novo* in a patient with rheumatic disease after the initiation of systemic therapy. The rapid advancement in the field of biologics and targeted therapies (e.g., tyrosine kinase inhibitors) for the treatment of rheumatic diseases requires pharmacovigilance for the skin as a frequent site of adverse effects. Finally, elucidation of the pathobiology of skin manifestations will undoubtedly provide important insight into the pathogenesis of rheumatic disorders and allow novel therapeutic approaches.

This chapter describes skin manifestations of the major systemic connective tissue disorders: systemic lupus erythematosus (SLE), dermatomyositis (DM), systemic sclerosis (SSc), and Sjögren syndrome (SJS). This is followed by a heterogeneous group of other systemic rheumatic diseases: rheumatoid arthritis (RA), psoriatic arthritis (PsA), systemic-onset juvenile rheumatoid arthritis (SOJRA), and relapsing polychondritis (RP). It is beyond the scope of this chapter to describe all rheumatic diseases with skin manifestations. The chapter starts with a section describing the general approach to patients with skin manifestations of a rheumatic disease.

APPROACH TO THE PATIENT

To assess skin involvement of a patient with rheumatic disease, a full-body inspection, including the scalp, anogenital area, and mucous membranes, should always be performed because the skin manifestations of rheumatic diseases often have a predilection for distinct body sites that can otherwise easily be overlooked. Examples of such situations are mucosal lesions in the oral cavity of patients with lupus erythematosus (LE) or intertriginous involvement by psoriasis in patients with arthritis. Inspection of all skin appendages (i.e., scalp hair and nails) is also an integral part of any routine dermatologic inspection. Notably, nail changes can be an important indicator of PsA, whereas scarring alopecia may be a troublesome skin manifestation of LE. Full-body inspection also enables the physician to determine the precise extent and severity of skin involvement in a rheumatic disease.

Accordingly, scores to assess the extent and severity of skin involvement have been developed for LE, SSc, and psoriasis and can be used to precisely monitor the efficacy of any treatment.

The skin changes as seen in systemic rheumatic diseases are said to be *specific* when they display characteristic and sometimes even pathognomonic features along with a typical histopathology encountered only in a distinct rheumatic disease. On the other hand, cutaneous manifestations can be *nonspecific* and occur in a diversity of rheumatic and nonrheumatic systemic diseases. It is also well established that some skin diseases have an increased incidence in patients with selected systemic rheumatic diseases. These dermatoses are best referred to as *associated skin diseases*. In some cases only the combination of specific and nonspecific skin changes in the presence of an associated skin disorder may establish the final diagnosis of a rheumatic disease. Description of the skin lesions encountered in patients with rheumatic diseases requires precise terminology. [Box 33.1](#) lists and explains common dermatologic terms encountered in this chapter.

A minimally invasive procedure (e.g., skin biopsy; see Chapter 32) is often helpful to precisely determine the nature of a skin lesion in patients with rheumatic disease. Although most skin lesions can easily be assessed by punch biopsies, involvement of deeper layers of the skin, such as in lupus panniculitis, requires deep incisional biopsies to not miss the diagnosis. Routine processing of skin biopsy specimens with paraformaldehyde fixation is usually sufficient to establish the diagnosis by histopathology, whereas cryopreservation is needed to visualize immunoglobulin deposits by specific staining. It is important to note that immunosuppressive or immunomodulatory treatment (systemic and topical) can severely mask the natural histopathologic picture of a specific skin lesion. Because of the turnover rate of human epidermis, cessation of any such treatment for at least 3 weeks is recommended before skin biopsy.

MAJOR SYSTEMIC CONNECTIVE TISSUE DISORDERS

Systemic lupus erythematosus

Key dermatologic signs of SLE include photosensitivity; malar dermatitis; discoid rash; other forms of specific cutaneous lupus erythematosus (CLE), localized or generalized, involving the epidermis, dermis, or subcutaneous fat of the skin; and oral ulcerations.

Skin involvement is the second most common manifestation of SLE after arthralgias. In approximately 25% of patients with SLE, skin is the first site of disease involvement. According to an Italian study, skin lesions develop in more than 75% of all patients with SLE during the course of their disease.¹ However, patients with SLE may have no signs of skin involvement, a condition called “*lupus sine lupo*.”

Classification of the skin manifestations of LE (CLE) is complex and may be a challenge, especially for novice and nondermatologist physicians. Precise description of the type of CLE is of importance because different subtypes have a different predisposition to systemic involvement of LE. Notably, different subtypes of CLE can occur both in patients with SLE and in patients with no systemic involvement.

The most widely accepted classification of LE was developed by Gilliam and Sontheimer.² It divides LE-specific skin disease into three major clinical subtypes according to their disease acuity: acute CLE (ACLE), subacute CLE (SCLE), and chronic CLE (CCLE) ([Box 33.2](#)).³ These subtypes are further specified according to the extent of their skin involvement (local vs. generalized), morphology, and localization of the inflammatory infiltrate in the skin (e.g., LE panniculitis indicating LE-specific infiltration of adipose tissue). It

BOX 33.1 FREQUENTLY USED DERMATOLOGIC TERMS

Erosion—a superficial tangential defect of the epidermis

Erythema—generalized erythema of the skin

Koebner phenomenon—induction of specific skin lesions by nonspecific trauma such as scratching

Macule—a flat localized discoloration of the skin; when the discoloration is red, it is called *erythema*.

Onychodystrophy—disturbed growth of the nail plate

Onycholysis—separation of the nail plate from the nail bed (hyponychium)

Papule/nodule/plaque—a raised, localized, solid skin lesion; when the raised lesion has spread horizontally, it is referred to as a *plaque*.

Pathergy phenomenon—induction of specific skin lesions by intracutaneous injection of sterile NaCl or as a result of venipuncture.

Poikiloderma—a combination of hyperpigmentation, hypopigmentation, telangiectasia, and skin atrophy

Purpura/petechia—localized intradermal hemorrhage; when less than 3 mm in diameter, it is called *petechial*.

Pustule—a vesicle filled with pus

Sclerosis—induration of the skin

Squama—localized area of abnormal shedding of the corneal layer of the epidermis

Ulcer—a substantial defect of the epidermis and deeper layers of the skin (dermis, subcutaneous tissue); it inevitably leads to scar formation.

Urtica/wheal—a transient raised skin lesion attributable to dermal edema; the center of the lesion is pale and the borders are erythematous.

Vesicle/bulla—a localized, raised lesion of the skin filled with exudate, either serous or hemorrhagic fluid; when larger than 0.5 cm in diameter, a vesicle is called a *bulla*.

Fig. 33.1 Generalized acute cutaneous lupus erythematosus. Note the typical distribution with sparing of the knuckles.

Fig. 33.2 Subacute lupus erythematosus (annular subtype). Note the characteristic localization on the upper part of the trunk (V shape).

BOX 33.2 CLASSIFICATION OF LUPUS ERYTHEMATOSUS-SPECIFIC SKIN LESIONS

- A. Acute cutaneous lupus erythematosus (ACLE)
 1. Localized ACLE
 2. Generalized ACLE
 3. Toxic epidermal necrolysis-like ACLE
- B. Subacute cutaneous lupus erythematosus (SCLE)
 1. Annular
 2. Papulosquamous
- C. Chronic cutaneous lupus erythematosus (CCLE)
 1. Discoid lupus erythematosus (DLE)
 - a. Localized
 - b. Generalized
 2. Hypertrophic/verrucous lupus erythematosus
 3. Lupus erythematosus tumidus
 4. Lupus panniculitis/profundus
 5. Chilblain lupus erythematosus
 6. DLE-lichen planus overlap

Modified from Sontheimer RD. Skin manifestations of systemic autoimmune connective tissue disease: diagnostics and therapeutics. *Best Pract Res Clin Rheumatol* 2004;18:429-62.

is important to note that in patients with SLE (as in patients with CLE only), different forms of LE-specific skin lesions can be present simultaneously (e.g., a butterfly rash as a manifestation of localized ACLE plus chilblain LE as a variant of CCLE).

The hallmark skin lesion of ACLE in patients with SLE is malar dermatitis, which is a reddish maculopapular eruption in a characteristic butterfly distribution on the face (see Fig. 126.1). In most cases patients recall induction or exacerbation of the rash by exposure to ultraviolet (UV) light, thus indicating that photosensitivity is an important diagnostic clue and pathogenetic component. Lesions tend to be transient, last from several hours to weeks, and heal without scarring. Occasionally, poikiloderma (characterized by dyspigmentation, prominent blood vessels, and thinning of the skin) can occur. When generalized, ACLE can involve the trunk with accentuation of the UV-exposed areas but may be localized elsewhere, including the hands, where the knuckles are typically spared (Fig. 33.1). A recently recognized life-threatening variant is toxic epidermal necrolysis-like ACLE. This condition may be regarded as a fulminant form of generalized ACLE in which a massive epidermal injury occurs, possibly because of severe alterations in the dermoepidermal junction and subsequent apoptosis. Another variant is

Rowell syndrome, which was originally described as an erythema multiforme-like eruption in patients with disseminated LE (DLE) and positive anti-Ro/La antibodies. However, subsequent reports and our own observations suggest that similar skin lesions can also develop in patients with SLE and SCLE, as well as in the presence or absence of anti-Ro/La antibodies. Oral lesions are a common mucocutaneous manifestation in patients with SLE and are part of the American College of Rheumatology (ACR) criteria. Typically, they consist of painful aphthoid lesions and ulcerations, especially on the lips and buccal and palatal mucosa, but they may be localized elsewhere in the oral cavity. Some palatal lesions may be asymptomatic.

Patients with clinical features of SCLE usually have circulating anti-Ro and anti-La antibodies and the HLA-B8 and HLA-DR3 haplotype. Notably, SCLE may be induced by drugs, especially antihypertensives and antifungals. This drug-induced type of SCLE does not appear to differ clinically, histopathologically, or immunologically from idiopathic SCLE.⁴ Two variants have been identified: an annular (or arcuate) variant consisting of slightly raised erythema with central clearing and a papulosquamous variant consisting of psoriasis-like or eczematous-like lesions, both typically located on UV-exposed skin, including the lateral aspects of the face, the V of the neck (often with sparing of the area under the chin), the upper ventral and dorsal part of the trunk (Fig. 33.2), and the dorsolateral aspects of the forearms. SCLE lesions never lead to scarring, but hypopigmentation or depigmentation as a result of postinflammatory destruction of epidermal melanocytes is a common complication during the healing process of these skin lesions (Fig. 33.3), especially in patients with darker skin phenotypes. A substantial proportion of patients with SCLE exhibit mild systemic symptoms, especially arthralgias and musculoskeletal complaints. Data from several studies indicate that the proportion of patients with SCLE fulfilling four or more ACR criteria for SLE ranges from 30% to 62%. Therefore,

Fig. 33.3 Residual vitiligo-like skin lesions in a patient with subacute cutaneous lupus erythematosus.

Fig. 33.4 Lupus erythematosus tumidus. Note urticarial plaques on the face and neck.

patients with SLCE need to be monitored closely during the course of their disease to exclude transition into SLE.

The prototypic skin lesion of the classic form of CCLE, also known as discoid CLE, is an erythematous discoid plaque that becomes hyperkeratotic and eventually leads to atrophy and scarring. This subtype of CLE occurs more often in black than in white individuals.³ Dyspigmentation, including hypopigmentation and hyperpigmentation, is common. Discoid lesions have a predilection for the face, ears, and neck but may be widespread without a clear-cut relationship to UV exposure. Disfigurement can be a serious problem, especially in patients with facial involvement. Mucosal membranes, including the lips, mucosal surfaces of the mouth, nasal membranes, conjunctivae, and genital mucosa, may also be involved with characteristic discoid lesions resembling leukoplakia. Although DLE is considered primarily a form of CLE without systemic involvement, patients with SLE may have classic DLE lesions. Long-term follow-up of patients with DLE is also necessary because according to retrospective analysis of a number of studies, SLE will develop in 5% to 10% in the course of the disease.

As outlined in Box 33.2, several other subtypes of CCLE can occur in patients with SLE and nonsystemic LE. In hypertrophic/verruccous CCLE, epidermal hyperkeratosis is prominent and results in lesions with thick scaling. LE tumidus is a rare variant of CLE characterized by photosensitive erythematous, sometimes urticarial plaques and nodules without epidermal hyperkeratosis or follicular plugging.⁶ Lesions are usually located on the face, upper part of the trunk, and extremities (Fig. 33.4). The majority of patients with LE tumidus do not have antinuclear antibodies, and diagnosis relies mainly on the clinical and histomorphologic picture. Because the course and prognosis of LE tumidus are generally more favorable than in other subtypes of CLE, it was suggested that this CLE subtype be labeled “intermittent subtype of CLE.”^{6,7} In contrast, LE panniculitis is a very

Fig. 33.5 Chilblain lupus erythematosus of the toes.

chronic CLE subtype consisting of intense inflammation within the adipose tissue of the skin that results in indurated plaques and lipoatrophy. Lesions are commonly seen on the face, proximal parts of the extremities, upper part of the trunk, and buttocks and can be disfiguring. When the overlying dermis and epidermis are involved in LE panniculitis, it is called *LE profundus*. As shown in a retrospective study of 40 patients with this CCLE variant, few patients (10%) fulfill the ACR criteria for SLE.⁸ Another variant of CCLE is chilblain LE, which denotes pernio-like skin lesions (i.e., red to violaceous plaques located on the distal parts of the extremities—fingertips, toes, and occasionally other parts of the body) that are typically induced and aggravated by exposure to cold (Fig. 33.5). These patients should be monitored carefully because SLE will develop in up to 24% of them.⁹

In the past, SLE disease activity, including some dermatologic criteria, has been assessed by various outcome measurements and scores. Recently, a “Revised CLE Disease Area and Severity Index (RCLASI)” has been introduced.¹⁰ This modified outcome instrument now includes the various CLE subtypes, as well as disease activity parameters (e.g., edema, scaling, hypertrophy, or dyspigmentation). The score had an intraclass correlation coefficient for an interrater reliability of 0.89 for the activity score and 0.79 for the damage score. The RCLASI may be used especially in clinical trials of patients with CLE to precisely assess skin involvement.

Histopathologic examination of a biopsy specimen from specific skin lesions may facilitate the correct diagnosis in a patient with LE. However, it should be noted that proper classification of the various CLE subtypes is based primarily on macroscopic skin morphology whereas the diagnosis of SLE relies on the overall clinical picture, including possible other organ manifestations and laboratory or serologic analysis. In acute forms of cutaneous involvement, LE-specific histologic changes can be subtle.ACLE lesions show vacuolar degeneration of the dermoepidermal junction, dead keratinocytes (“Civatte bodies”), and a sparse lymphohistiocytic infiltrate of the upper dermis. Dermal blood vessels are dilated with extravasation of erythrocytes. In SCLE, these findings are often associated with epidermal atrophy. The lymphohistiocytic infiltrate is located in the upper dermis with an interface and perivascular pattern. Classic DLE lesions have additional epidermal hyperkeratosis and thickening of the dermoepidermal and follicular basement membranes. The lymphohistiocytic infiltrate is often prominent and involves hair follicles, which may also show hyperkeratotic plugging. Mucin may be deposited in the dermis. Deeper forms of CCLE are characterized by a lymphohistiocytic infiltrate situated in the lower dermis, often with mucin deposits (LE tumidus), whereas in lupus panniculitis, the infiltrate is located primarily in the subcutaneous fat tissue. Direct immunofluorescence (DIF) can be used to assess the presence of immunoglobulin (IgG, IgM, and rarely IgA) and complement (C3) along the dermoepidermal junction in frozen sections of CLE lesions. In patients with SLE, this test (“lupus band test”) is typically positive even in nonlesional, sun-protected skin. However, DIF studies currently provide little benefit to the overall diagnosis and classification of LE and may be used only to discriminate between CLE and skin diseases with similar histopathologic findings.

The differential diagnosis of ACLE lesions includes erythema solare (sunburn), photoallergic and phototoxic drug eruptions, DM, atopic eczema, seborrheic dermatitis, contact eczema, and rosacea. SCLE lesions need to be

distinguished from photoallergic and phototoxic drug eruptions, as well as from other forms of annular erythemas (erythema annulare centrifugum, erythema gyratum repens, granuloma annulare, eczema, psoriasis, and tinea). Leukoderma in patients with SLE must not be mistaken for vitiligo, whereas hyperpigmented skin lesions in patients with chronic DLE (CDLE) have to be distinguished from other forms of hyperpigmentary skin diseases.

In addition to the previously described LE-specific skin lesions, a plethora of nonspecific skin signs and associated skin diseases can be present in patients with SLE. These skin signs include harmless vascular changes such as nail-fold abnormalities (large and tortuous capillaries together with areas of avascularity), as well as more serious complications such as vasculitis (leukocytoclastic vasculitis, urticarial vasculitis, nodular vasculitis) and other forms of vasculopathy (atrophie blanche, livedo reticularis, Degos-like lesions, ulcerations, and thromboses), the latter developing especially in patients with antiphospholipid syndrome. Nonscarring alopecia (“lupus hair”) may be seen in patients with SLE, whereas scarring alopecia typically occurs in patients with DLE involving the scalp. Raynaud phenomenon, calcinosis cutis, scleroderma-like changes, and rheumatoid nodules may indicate the presence of an overlap syndrome.

Dermatomyositis

Key dermatologic signs of DM include heliotrope rash, Gottron papules, Gottron sign, poikiloderma atrophicum vasculare, periungual telangiectases, dystrophic cuticles, and calcinosis cutis.

Involvement of the skin is essential in making the diagnosis of DM because characteristic cutaneous lesions belong to the diagnostic criteria for DM according to Bohan and Peter.¹¹ Importantly, skin manifestations precede the clinical symptoms of muscle weakness, electromyopathic abnormalities, or increased levels of creatine phosphokinase in 30% of patients with DM, and in 10% to 20% of all patients with DM, specific skin changes may occur for longer than 6 months without systemic involvement. This group of patients has been referred to as having *amyopathic DM* (DM sine myositis). Although a variety of skin manifestations occur in DM, none of the skin signs allows discrimination between idiopathic DM and the paraneoplastic form.

One highly specific skin sign that can be regarded as the cutaneous hallmark feature of DM is the heliotrope rash (Fig. 33.6). This often pruritic, sometimes burning, violaceous, confluent erythema resembles the color of the heliotrope, a pinkish purple flower that tracks the course of the sun. The heliotrope rash of DM has a characteristic distribution that especially involves the periorbital area. Other sites of predilection are the malar area of the face, the posterior aspect of the neck and shoulders (referred to as the “shawl sign”), and the scalp. DM also often affects the extensor surfaces of the extremities, the knuckles, the dorsal aspects of the interphalangeal joints, and the periungual area of the fingers in a symmetric fashion (see

Fig. 33.6 Heliotrope rash on the face in a man with dermatomyositis.

Fig. 148.1). The characteristic violaceous color and the periorbital distribution of the heliotrope rash distinguish DM from the butterfly rash (malar rash) of ACLE. It is also important to recognize that the skin lesions of DM, when affecting the fingers, tend to be located over the joints and not on the interphalangeal areas, as in patients with generalized ACLE (compare Figs. 33.1 and 148.1).

Depending on the intensity of inflammation, the violaceous macules of DM may evolve into plaques that are often covered with a fine silvery scale, especially on the knees and elbows. When such lesions occur over the knuckles, in the interphalangeal joints, and in the periungual area, they are known as *Gottron papules* (see Fig. 148.1). Violaceous macules developing over the knuckles and the elbows or knees have been referred to as the *Gottron sign* (Fig. 33.7). The intensely inflamed skin lesions of DM may develop into erosions, subepidermal blisters, and ulcers (Fig. 33.8). Recently, the presence of antimelanoma differentiation-associated gene 5 (*MDA5*) has been reported to identify the presence of characteristic skin lesions and musculoskeletal, pulmonary, and prognostic features in Japanese patients with DM.¹² Patients with these antibodies had multiple pustules and ulcers on their fingers and palms. Mortality was independently associated with the presence of anti-MDA5 antibodies.

Furthermore, the term *poikiloderma atrophicum vasculare* has been coined to describe patients with DM and a combination of violaceous erythema, hyperpigmentation, hypopigmentation, telangiectasia, and atrophy.

In addition to the aforementioned skin signs, many patients with DM have prominent nail-fold telangiectases (see Fig. 148.8) and dystrophic (“ragged”) cuticles. Moreover, gingival telangiectases have recently been identified as a sign of juvenile DM. Other, less frequently encountered cutaneous manifestations of DM include panniculitis leading to lipotrophy, papular and pustular lesions, and centripetal flagellate erythema. The term *mechanic’s hands* (see Fig. 148.9) has been applied to the occurrence of

Fig. 33.7 Violaceous plaques on the knees of a patient with dermatomyositis (Gottron sign).

Fig. 33.8 Skin ulcerations in a young female with paraneoplastic dermatomyositis.

chronic eczematous skin lesions on the fingers of patients with myositis.¹³ A high proportion of patients with mechanic's hands turned out to have so-called *antisynthetase syndrome* (an overlap syndrome consisting of anti-synthetase antibodies, erosive polyarthritis, interstitial lung disease, fever, Raynaud phenomenon, and inflammatory myositis). Another subset has anti-PM-SCL antibodies, indicative of a polymyositis-scleroderma overlap syndrome. However, recent observations have questioned the specific association of the previously mentioned antibodies with mechanic's hands, thus suggesting that these skin manifestations may also occur in related systemic connective tissue disorders.

Calcinosis cutis can be an extremely painful and devastating skin manifestation of DM. It occurs most often at sites of friction and trauma, such as on the elbows, trochanters, knees, and fingers, and consists of hard, irregular nodules that eventually drain chalky material to the skin surface. It is more prevalent in juvenile DM than in the adult form. Of note, calcinosis is also a key feature of the calcinosis, Raynaud phenomenon, esophageal hypomotility, sclerodactyly, telangiectasia (CREST) syndrome and can be a manifestation of overlap syndromes.

Histopathologic examination of a heliotrope erythema typically reveals an interface dermatitis with a sparse lymphocytic infiltrate, epidermal atrophy, vacuolar alteration of the basal keratinocytes, basement membrane degeneration, and interstitial mucin deposition. More inflamed lesions (i.e., Gottron papules) also show lichenoid infiltrate and acanthosis of the epidermis. Immunohistologic studies have demonstrated that the infiltrate in skin and muscle lesions of patients with DM consists mainly of CD8+ lymphocytes, thus supporting the concept of a lymphocyte-mediated disease in the pathogenesis of DM.

The differential diagnosis of DM includes SLE, psoriasis, atopic dermatitis, photoallergic and phototoxic drug eruption, contact dermatitis, cutaneous T-cell lymphoma, SSc, and trichinosis. The skin ulcers in DM need to be distinguished from hemorrhagic-necrotizing vasculitis and from a DM-like eruption with painful ulcerations induced by hydroxyurea.

Systemic sclerosis

Key dermatologic signs of SSc include Raynaud phenomenon, symmetric cutaneous sclerosis, finger swelling, sclerodactyly, digital pits and ulcers, dilated or atrophic nail-fold capillaries, calcinosis cutis, and hyperpigmentation.

The term *sclerosis* describes hardening or induration as a result of excessive deposition of interstitial collagen and subsequent tissue fibrosis. By definition, SSc is a multisystem disorder that involves the skin and internal organs. However, it should be noted that sclerosis of the skin ("scleroderma") is a common reaction pattern of several fibrotic skin disorders, some of which are benign and localized only to the skin whereas others are systemic conditions. Thus, in the context of the clinical pattern, internal organ abnormalities, and laboratory tests, the diagnosis of SSc should always exclude these differential diagnoses (see later).

There is striking heterogeneity within the clinical spectrum of cutaneous thickening in patients with SSc, but two subtypes with distinct clinical, serologic, and prognostic features have been delineated. In patients with *diffuse* SSc, skin thickening involves the trunk and proximal portions of the extremities, whereas in patients with *limited* SSc, the skin induration is confined to the face and distal portions of the extremities. However, there are cases with overlap between these two widely accepted clinical forms of SSc. A distinct form of limited SSc with induration of the fingers ("sclerodactyly") is the CREST syndrome. These patients typically have detectable anticentromere antibodies and a generally favorable prognosis when compared with patients with diffuse SSc. Finally, an unusual variant called *scleroderma sine scleroderma*, in which affected patients have evidence of SSc secondary to SSc-related antibodies and internal organ involvement but no skin involvement, has been described. The prognosis of these patients is similar to those with limited SSc.

Often years before the onset of skin induration, patients with SSc experience Raynaud phenomenon (see Figs. 142.2 and 142.3). Although a non-specific sign that is seen in other connective tissue diseases and closely related overlapping syndromes, Raynaud phenomenon is present in 90% to 99% of patients with diffuse or limited SSc. When cutaneous involvement proceeds, an edematous phase of the affected sites often takes place, especially on the fingers ("puffy fingers"). Similar changes may also be seen on the forearms, legs, feet, face, and trunk. This is followed by gradual thickening of the skin in which the initial inflammation is replaced by interstitial fibrosis caused by abnormal collagen metabolism (indurative phase) and subsequent sclerodactyly and dermatopathic contractures. The impaired acral blood flow in sclerodactyly may lead to digital pits and ulcers (see Fig. 142.4). A recent study further revealed that patients with SSc and digital

ulcers exhibited internal organ involvement 2 to 3 years earlier than did those without digital ulcers.¹⁴

Among the other common cutaneous key signs of SSc are telangiectases, which also form a diagnostic cornerstone in patients with CREST syndrome. The telangiectases seen in patients with SSc are often located on the face, including the lips, but may also be detected on the neck, volar aspects of the fingers, and palms and tend to be matted (see Fig. 142.11). Dilated nail-fold capillaries, often alternating with areas of capillary loss, can easily be detected with a dermatoscope. Calcinosis is another key feature of CREST syndrome and tends to be located on the extremities, especially at the fingertips and over joints (Fig. 33.9).

A relatively unappreciated skin sign in patients with SSc is skin hyperpigmentation. It occurs mostly as a diffuse brownish discoloration resembling a suntan and is usually accentuated in areas of friction and pressure (Fig. 33.10). Variants of skin discoloration in patients with diffuse SSc do occur and include "salt and pepper," which describes a combination of hyperpigmentation and hypopigmentation often found on the upper part of the trunk (see Fig. 33.10).

Although a number of instrumental devices such as a skin durometer and 25-MHz ultrasonography may be useful to determine the extent of skin sclerosis in patients with SSc, the modified Rodnan total skin thickness score remains an essential tool for daily routine, as well as for clinical trials. This score assesses cutaneous thickening on a scale of 0 to 3 in 17 anatomic areas by means of palpation.¹⁵ However, interobserver variability is high (mean, 17.7), and proper application of this tool in patients with SSc still requires some training.

Histopathologic examination of sclerotic skin from patients with SSc demonstrates excessive collagen deposits within the dermis and subcutaneous tissue that often entrap the adnexal structures as the predominant

Fig. 33.9 Calcinosis cutis.

Fig. 33.10 Diffuse hyperpigmentation of the skin in a patient with systemic sclerosis. Note also the depigmentation in the submammary region.

finding. In earlier inflammatory phases (edematous phase), a dense lymphocytic infiltrate may be seen at the interface of the deep dermis and adipose tissue.

The differential diagnosis of SSc includes scleromyxedema; eosinophilic fasciitis (Shulman syndrome); scleredema adutorum and diabeticorum; diabetic thick skin; sclerosing chronic graft-versus-host disease; sclerosing forms of porphyria; polyneuropathy, organomegaly, endocrinopathy, *M* component, and skin changes (POEMS syndrome); nephrogenic fibrosing dermopathy; eosinophilia myalgia syndrome; toxic oil syndrome; carcinoid syndrome; pansclerotic localized scleroderma (morphea); exposure to bleomycin, aromatic chlorinated hydrocarbons, or vinyl chloride; phenylketonuria; various progeria syndromes; and reflex sympathetic dystrophy.

Sjögren syndrome (Mikulicz disease, sicca syndrome)

Key dermatologic signs of SjS include xerostomia, xerosis cutis, angular stomatitis (perlèche), various forms of cutaneous vasculitis, and annular erythema.

Mucocutaneous symptoms are usually the first clinical findings in patients with SjS, a systemic autoimmune disorder that primarily affects the secretory glands. Though a nonspecific sign, dryness (xerosis) of the mucous membranes in context with the other diagnostic criteria is a key component for establishing the diagnosis of this multisystem disease. Xerosis can involve not only the mouth (xerostomia) and the eyes (leading to keratoconjunctivitis sicca) but also the vagina. Regarding the mouth, patients typically complain of dryness, soreness, and burning sensations. Vaginal xerosis can likewise result in dryness, burning, and dyspareunia, but patients frequently do not report these symptoms unless asked specifically about them. Because of diminished salivary production, angular stomatitis (perlèche) of the mouth with *Candida* infection is common. Although dental and gingival problems are said to be more frequent in patients with SjS, a recent study did not indicate any increased risk for caries and gingivitis, probably because of increased awareness and dental care of affected patients.¹⁶

In addition to the aforementioned key signs in the mucous membranes, several *bona-fide* skin manifestations are frequently observed in patients with SjS. All of them are again nonspecific. Xerosis cutis is found in 50% of patients, but the underlying pathomechanism remains obscure. It may lead to generalized pruritus. In the authors' experience, various forms of noncutaneous vasculitis, most likely resulting from an immune complex mechanism, are frequently encountered in patients with SjS. They include palpable and nonpalpable purpura on the legs and buttocks (see Fig. 138.5). This form of cutaneous vasculitis is characteristically induced or aggravated by physical exertion. Other forms of cutaneous vasculitis include lymphocytic vasculitis and urticarial vasculitis (either hypocomplementemic or, less commonly, normocomplementemic). By definition, the urticarial lesions of urticarial vasculitis last longer than 48 hours (in contrast to common urticaria) and often have a purpuric component. Patients frequently complain of burning and painful sensations. The lesions often heal with hyperpigmentation. Histologically, the lesions of lymphocytic vasculitis display a mononuclear cell infiltration with disruption of the architecture of the small blood vessels, whereas those of leukocytoclastic vasculitis, including urticarial lesions, show the expected well-described changes.

An unusual skin manifestation of SjS was originally described in Japanese children and has been coined annular erythema of SjS. It appears to be highly associated with the presence of anti-Ro antibodies. Clinically and histologically, these lesions may be indistinguishable from annular SCL. Recent observations indicate that identical lesions can also occur in white individuals.

Regarding other cutaneous manifestations, it is important to note that SjS can be not only primary but also secondary and therefore associated with a number of other diseases, including LE, DM, SSc, RA, primary biliary cirrhosis, fibromyalgia, and others. The specific skin signs of these associated disorders must therefore be distinguished from the *bona-fide* skin manifestations of SjS.

OTHER SYSTEMIC RHEUMATIC DISEASES

Rheumatoid arthritis

Key dermatologic signs of RA include nodules, often symmetrically distributed, purpura, petechiae, and ulcerations.

The characteristic clinical features of RA are frequently associated with skin manifestations, which may not only serve as helpful diagnostic clues

but also indicate the severity of the disease. Rheumatoid nodules, accelerated rheumatoid nodulosis, rheumatoid neutrophilic dermatosis, and rheumatoid vasculitis are regarded as RA-specific skin manifestations.

Classic *rheumatoid nodules* are present in about 25% of patients with RA and are more frequent in the white male population.¹⁷ Most patients with rheumatoid nodules are rheumatoid factor positive. In seronegative RA, the nodular lesions turned out to be mostly granuloma annulare or other palisading granulomas. Genetic predisposition seems to play a role because patients with the HLA-DR4 haplotype and those with heterozygosity for HLA-DRB1 alleles are at high risk for nodular disease, as well as a severe RA prognosis.¹⁸ Rheumatoid nodules measuring from a few millimeters up to several centimeters generally develop as subcutaneous, firm, and painless lesions. Usually they occur on periarticular locations over extensor surfaces, but they may appear in any location, including the lung, heart, and muscle. Complications that may sometimes occur include infection, ulceration, gangrene, bursitis, and synovial rupture.

The differential diagnosis of rheumatoid nodules includes chronic gouty tophi, rheumatic fever nodules, the subcutaneous nodules found in SLE, nodular or keloidal scleroderma, and the nodules seen in necrobiosis lipoidica and granuloma annulare. In addition, tumoral calcinosis, fibromas, xanthomas, subcutaneous sarcoidosis, metastatic tumors, amyloidosis, ganglion cysts, foreign-body granulomas, basal cell carcinomas, epidermoid cysts, and synovial cysts should be considered.

The characteristic symptomatic complex of arthritis, leukopenia, and splenomegaly, which develops in 1% of patients with RA, is known as *Felty syndrome*. Rheumatoid nodules (76%), hyperpigmentation, and therapy-resistant leg ulcers (22%) may also occur.¹⁹ However, cutaneous hyperpigmentation and leg ulceration may be multifactorial and are often related to underlying chronic venous insufficiency. Importantly, Felty syndrome is associated with an increased risk for cutaneous and systemic infections that may be difficult to treat and be the cause of sepsis. The differential diagnosis includes SLE, drug-induced leukopenia, viral infection, amyloidosis, leukemia, lymphoma, subacute bacterial endocarditis, aplastic anemia, splenic abscess, hemolytic anemia, tuberculosis, and SjS. In addition, cutaneous ulcerations and hyperpigmentation may also be caused by systemic treatment with methotrexate (MTX).

Accelerated rheumatoid nodulosis was initially reported in patients receiving MTX therapy for RA or juvenile rheumatoid arthritis.²⁰ It is characterized by the development of painful nodules mainly on the hands of RA patients being treated with MTX; it has not been found to be associated with other immunosuppressive drugs such as azathioprine. RA patients treated with hydroxychloroquine, D-penicillamine, colchicine, or sulfasalazine were found to be protected against the development of MTX-induced accelerated rheumatoid nodulosis. Interestingly, the occurrence of similar nodules has been observed during MTX therapy in a patient with PsA. Recently, accelerated rheumatoid nodulosis has also been described in patients receiving etanercept,²¹ as well as in one patient receiving an aromatase inhibitor,²² thus indicating that MTX is not the only trigger eliciting such skin manifestations of RA. Like other granulomatous skin manifestations of RA (see later), infections by typical and atypical mycobacteria, as well as by opportunistic or endemic bacteria, have to be excluded, especially in patients taking immunosuppressants.

Rheumatoid vasculitis is a late complication of RA that may involve the skin, as well as other organs, and may affect vessels of any size. Accordingly, rheumatoid vasculitis can result in a variety of cutaneous skin signs (Box 33.3). It occurs in seropositive and mainly male RA patients with longstanding disease.²³ Small-vessel disease clinically represents palpable and nonpalpable purpura, localized petechiae, splinter hemorrhages, nail-fold infarctions (Bywaters lesions), and peripheral neuropathy. In medium-vessel disease, cutaneous findings include nodules, ulcerations, livedo reticularis, and digital infarcts. Because the course of rheumatoid vasculitis is associated with high morbidity and mortality, early and intensive immunosuppressive therapy is required. Biopsy of cutaneous lesions, preferentially nodules, and immunohistochemical examination are often helpful in establishing the diagnosis. Because peripheral neuropathy is frequently observed in cases in which vasculitis cannot be identified, nerve conduction studies and sural nerve or muscle biopsy can be performed. The differential diagnosis of rheumatoid vasculitis includes polyarteritis nodosa, PG, SLE, antineutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis, and erythema elevatum et diutinum.

In addition to the previously mentioned specific skin manifestations of RA, large numbers of nonspecific skin signs and associated dermatoses have been described (Box 33.4). *Pyoderma gangrenosum* is frequently associated with both seronegative and seropositive RA. Clinically, it begins as a tender erythematous or violaceous papule that expands rapidly into a purulent necrotic ulcer with ragged edematous edges (Fig. 33.11). Usually, PG occurs

BOX 33.3 SKIN MANIFESTATIONS OF RHEUMATOID VASCULITIS

Petechiae or purpura
 Digital infarcts
 Nail-fold telangiectases and infarctions
 Gangrene
 Nonspecific maculopapular or nodular erythema

as a single painful lesion on the lower extremities. Koebner and pathergy phenomena are characteristic. The presence of chronic relapsing lesions in unusual sites such as the face, upper extremities, or abdomen may indicate another underlying disease such as inflammatory bowel disease or hematologic disorders. The idea that PG is a true skin manifestation of RA has been challenged because it also occurs in other systemic disorders, has no relationship in its clinical manifestation with the course of RA, and involves no

Fig. 33.12 Rope sign in a patient with interstitial granulomatous dermatitis.

histology specific for RA.²⁴ Histologic examination of early lesions demonstrates a neutrophilic infiltrate and small abscesses.

The differential diagnosis of PG includes venous or arterial ulcers, vasculitis, drug reactions, antiphospholipid syndrome, halogenoderma, factitial diseases, deep fungal infections, mycobacterial infections, gummatous syphilis, viral infections, amebiasis, arthropod bites, and tumors.

Rheumatoid neutrophilic dermatosis is a rare cutaneous sign in patients with severe and seropositive RA.²⁵ Clinically, it is manifested as asymptomatic erythematous urticarial papules and plaques that may persist and sometimes ulcerate. They are usually distributed on the forearms and hands. Rheumatoid neutrophilic dermatosis resembles Sweet syndrome.

Palisaded neutrophilic and granulomatous dermatitis, also known as Winkelmann granuloma, represents a condition of unknown cause with a variety of clinical findings in the context of systemic diseases. Skin manifestations usually develop symmetrically on the extensor surfaces of the elbows and fingers and appear as skin-colored, erythematous, or violaceous papules, nodules, and plaques, sometimes with central umbilication and crusts or perforation.²⁶ Histopathologic examination shows granulomatous inflammation in the presence or absence of leukocytoclastic vasculitis. In addition to RA, this condition has been especially associated with Behçet disease, SLE, SSC, ulcerative bowel and celiac disease, sarcoidosis, ANCA-associated vasculitis ("Wegener granulomatosis"), and lymphoproliferative disease.

Another skin sign of RA may be *interstitial granulomatous dermatitis*.²⁷ It consists of multiple well-demarcated erythematous to violaceous papules or plaques, sometimes coalescing to larger areas or linear cords (Fig. 33.12). However, the latter distinctive pattern ("rope sign") is seen in only 10% of all cases.²⁸ Lesions are typically located on the trunk but may also occur on the proximal ends of limbs. They may perforate with extrusion of the necrobiotic collagen. Histopathologically, the lesions consist of a predominantly CD68+ inflammatory infiltrate of macrophages between collagen bundles in the mid and deep dermis. The macrophages are surrounded by degenerated collagen fibers, and no signs of vasculitis or mucin deposition are present. Giant multinucleated histiocytes are detectable in only a subset of cases.²⁸ It is important to note that this condition is associated not only with RA or other forms of arthritis or arthralgias but also with other autoimmune diseases and with cancer.²⁸ The differential diagnosis of the granulomatous dermatitis of RA includes mainly granuloma annulare, necrobiosis lipoidica, granulomatous slack skin, and interstitial granulomatous drug reactions.

Systemic-onset juvenile rheumatoid arthritis (juvenile rheumatoid arthritis, juvenile chronic arthritis, Still disease)

Key dermatologic signs of SOJRA include macular or maculopapular exanthema and rheumatoid nodule-like lesions.

Fig. 33.13 Exanthema in a child with Still disease.

Diagnosis of SOJRA can be challenging. Because skin manifestations can precede the arthralgias by years, early recognition can be crucial in establishing the diagnosis. SOJRA has two clinical manifestations: an acute febrile systemic variant and an oligoarticular variant with low-grade persistent fevers. In the acute-onset variant, in which high episodic fevers with temperatures higher than 38.9° C are characteristic, a nonpruritic transient exanthema that recurs with fevers develops in 90% of patients.²⁹ It consists of discrete macular or maculopapular lesions, often located on the trunk (Fig. 33.13). The color of the lesions is pink to red, and koebnerization is common. The histopathologic findings of the rash are nonspecific and consist of a discrete perivascular mixed infiltrate with edema of the upper dermis. Another skin sign in patients with SOJRA is rheumatoid nodule–like lesions with a predilection for the extensor surfaces of the extremities.³⁰ Lesions can be both clinically and histologically indistinguishable from those in patients with RA.

The differential diagnosis of the typical exanthema of SOJRA in combination with fever and arthralgias includes rheumatic fever, familial Mediterranean fever, hyper-IgD syndrome, tumor necrosis factor receptor–associated periodic syndrome (TRAPS), familial Hibernian fever, autosomal dominant periodic fever with amyloidosis, and benign autosomal dominant familial periodic fever.

Relapsing polychondritis (atrophic polychondritis, systemic chondromalacia, polychondropathia)

Key dermatologic signs of RP include erythema, swelling, and pain in the cartilaginous portion of the ear with sparing of the earlobe, as well as auricular and nasal deformity.

RP is a chronic inflammatory multisystem disorder that can lead to significant morbidity because of destruction of the cartilaginous tissue in many organs. In a significant number of patients with RP, cutaneous involvement is the first clinical manifestation.

The hallmark cutaneous features of RP are erythema, swelling, and pain in the cartilaginous part of the ear that typically spares the earlobe (see Fig. 167.1). The vast majority of patients with RP suffer from auricular involvement during the course of their disease. Persistent inflammation will lead to destruction of the auricular cartilage and result in so-called cauliflower ears. Involvement of the nasal cartilage occurs in 70% of affected patients and eventually leads to a saddle nose deformity.³¹ Glomerulonephritis may accompany RP.

Histopathologic examination of inflamed cartilage shows basophilic staining, loss of the normal lacunar structures, and a neutrophilic infiltrate. At later stages, lymphocytes and plasma cells are more prominent and the cartilage is replaced by granulation tissue and fibrosis.

Several nonspecific skin signs have been reported to occur in 36% of patients with RP.³² However, a significant proportion may be related to associated diseases (myelodysplastic syndrome, Behçet disease, and other systemic disorders) or adverse effects of concomitant systemic treatment. These skin manifestations consist of various forms of vasculitis, including palpable purpura, and erythema elevatum et diutinum, noninflammatory vasculopathies like livedo reticularis, furthermore, panniculitis, and aphthosis (oral or complex).

The differential diagnosis of RP includes primarily traumatic and infectious forms of chondritis and ANCA-associated granulomatous vasculitis,

Fig. 33.14 Psoriasis vulgaris. Note the typical distribution over the extensor surfaces and silvery scales.

Fig. 33.15 Psoriasis vulgaris involving the scalp (psoriasis capitis).

which may also lead to cartilage destruction, especially of the nose. The combination of features of RP and Behçet disease has led to the designation mouth and genital ulceration with inflamed cartilage (MAGIC syndrome).³³

Psoriatic arthritis

Key dermatologic signs of psoriasis are papulosquamous plaques on the scalp and on the extensor surfaces of the body as well as nail dystrophy. Psoriasis, one of the most common immune-mediated inflammatory skin disorders with an estimated prevalence of 2% in Europe,³⁴ has to be excluded in all patients with arthralgia. Although clinical diagnosis of psoriasis is easy in most cases, it can be challenging in patients with less frequent psoriasis subtypes as well as in those receiving immunosuppressive agents. Moreover, the dermatologic manifestations of psoriasis are quite heterogeneous. Classification of the clinical subtypes of psoriasis is traditionally based on morphology, localization, and extent of the disease, with current concepts also trying to incorporate disease stability and numeric parameters.³⁵

The most common form of psoriasis is known as *psoriasis vulgaris* or *plaque psoriasis*. Its key feature is a sharply demarcated red to pinkish papulosquamous plaque of any size with a noncoherent silvery scale (Fig. 33.14). Involvement of the scalp by psoriasis appears to particularly be associated with PsA (Fig. 33.15).³⁶ On removal of the scale a glossy erythema with blood droplets appears (Auspitz sign). Typically, the elbows, knees, lower part of the back, scalp including the ears, and umbilicus are involved. The palms and soles may be affected as well. Within the psoriasis vulgaris group two subtypes had already been distinguished more than 20 years ago. In the first group (type I), the peak onset of psoriasis occurs at an age of 16 years (females) or 22 years (males), and in the second group (type II) the peak onset occurs at an age of 60 years (females) or 57 years (males).³⁷ Patients

Fig. 33.16 Nail psoriasis. Note the onycholysis, oil spots, and pits.

Fig. 33.17 Psoriasis inversa. Note well-demarcated erythema and absence of scales.

classified as having type I psoriasis vulgaris have a genetic association within the major histocompatibility complex class I region on chromosome 6p (HLA-Cw*0602), whereas patients classified as having type II have no evidence of association with HLA-C alleles.³⁸

Guttate psoriasis (from Latin *guttata*, meaning “droplike”) may be considered a subtype of type I psoriasis vulgaris and is often encountered in children and young adults. In this case the psoriasis develops as an acute eruption of papules and plaques measuring less than 1 cm that most often starts on the trunk but may spread to the proximal parts of the extremities and face. Infections with group B hemolytic streptococci (tonsillitis, pharyngitis) may precede the development of guttate psoriasis, especially in children and young adults. Even though this form of psoriasis is said to be self-limited and resolves within 3 to 4 months, few data are available on the long-term risk for the development of chronic plaque psoriasis after a single episode of guttate psoriasis.³⁹

Nail psoriasis can be considered an important indicator of PsA. Although it occurs in 40% to 45% of patients with psoriasis without joint involvement, its prevalence is 60% to 90% in those with PsA.⁴⁰⁻⁴² Typical features are oil spots (yellow to orange subungual discolorations), pits (punctate nail plate defects), onycholysis, and onychodystrophy (Fig. 33.16). Interestingly, nail psoriasis may be present without additional signs of skin involvement.

In addition to manifestation of psoriasis on the scalp and nails, involvement of the flexural or intertriginous areas may alert the clinician to PsA.³⁶ This type of psoriasis has been coined *psoriasis inversa* and describes the localization of psoriatic lesions in the groin, axilla, submammary region, natal cleft, and genital area. The lesions are typically erythematous with little or no scaling and tend to be associated with maceration and fissuring (Fig. 33.17).

Psoriatic erythroderma describes total involvement of the skin with psoriasis. It is characterized by generalized erythema and various degrees of scaling, depending on the course of development either as an abruptly evolving psoriasis or as a complication of preexisting, slowly progressive plaque psoriasis. Psoriatic erythroderma must be considered a potentially life-threatening condition associated with hypothermia, hypoalbuminemia, and tachycardia. It may lead to high-output cardiac failure, especially in multimorbid patients.

Pustular psoriasis occurs as a limited eruption of sterile pustules on the palms and soles (psoriasis pustulosa palmoplantaris) or as a generalized form (von Zumbusch psoriasis). The latter is an acute, often febrile eruption of multiple monomorphic sterile pustules on erythematous skin, especially over the trunk and extremities, and is associated with systemic illness. Although psoriasis pustulosa palmoplantaris is frequently found in patients with psoriasis vulgaris, genetic studies point toward a different pathogenesis.⁴³

Assessment of the extent, severity, and acuity of skin involvement by psoriasis can be done with various outcome tools, including the Psoriasis Area and Severity Index, Overall Lesion Severity instrument, physician global assessment, and assessment by affected body surface area. Because psoriasis can severely affect quality of life, patient-related outcome tools are likewise important. For nail involvement, a Nail Psoriasis Severity Index has also been developed.⁴⁴

The diagnosis of psoriasis is made primarily clinically, and skin biopsy is not usually required. If biopsied, early psoriasis lesions show a modest lymphocytic perivascular infiltrate with prominent vessels in the upper dermis. Later, extravasation of erythrocytes occurs with mild epidermal hyperplasia. Scalp lesions reveal epidermal parakeratosis and hyperplasia, prominent mitoses in basal keratinocytes, and neutrophilic infiltration. The neutrophils migrate into the epidermis (Munro microabscesses). Fully developed psoriasis lesions show elongation of the rete ridges, mounds of parakeratosis, and more prominent accumulation of neutrophils. Vessels in the papillary dermis are tortuous and dilated with extravasation of both erythrocytes and lymphocytes.

The differential diagnosis of psoriasis vulgaris includes tinea corporis, papulosquamous SCLE, mycosis fungoides, pityriasis versicolor, pityriasis rubra pilaris, secondary syphilis, and eczema. Psoriasis of the scalp must be distinguished from DLE and tinea capitis, whereas nail psoriasis must be differentiated from tinea unguium. Psoriasis inversa may be mimicked by intertrigo, candidiasis, and Hailey-Hailey disease. Psoriatic erythroderma must be differentiated from other forms of primary (drug-induced) and secondary erythroderma (caused by nonpsoriatic immune-mediated inflammatory skin diseases). Pustular psoriasis needs to be distinguished from bacterial skin infections and other noninfectious pustuloses of the skin.

The eye in rheumatic disease

■ JENNIFER E. THORNE ■ DOUGLAS A. JABS

- Ocular inflammation is common in rheumatic disease and often varies with the rheumatic disease in question.
- The most common ocular manifestations of rheumatic disease are uveitis, scleritis, and keratoconjunctivitis sicca.
- In selected rheumatic diseases (i.e., antineutrophilic cytoplasmic antibody–associated granulomatous vasculitis, Behçet disease), the eye disease may be severe enough to dictate therapy for the systemic disease.

INTRODUCTION

The rheumatic diseases are a heterogeneous collection of immune-mediated, multisystem disorders. Ocular involvement is common and often varies with the rheumatic disease in question.¹ The major manifestations of ocular involvement in rheumatic disease include uveitis, scleritis, retinal vascular disease, neuroophthalmic lesions, orbital disease, keratitis, and sicca disease associated with Sjögren syndrome.¹ The eyes may also be affected by several drugs used for the treatment of inflammatory rheumatic diseases, such as corticosteroids or antimalarial agents; these abnormalities are discussed in the appropriate chapters.

UVEITIS

Uveitis refers to a group of approximately 30 diseases characterized by inflammation inside the eye, some of which are infectious, some associated with systemic diseases, and many of which are eye-limited, immune-mediated disorders. Each disease has its own features, course, treatment, and prognosis. The uveitides are classified by the anatomic site at which the inflammation primarily occurs. Uveitis detected primarily in the anterior chamber is termed *anterior uveitis* (Fig. 34.1), which is also known as *iritis* or *iridocyclitis*. Inflammation primarily involving the vitreous is termed *intermediate uveitis*, and uveitis located in the retina or choroid is called *posterior uveitis*. Uveitis that involves all three compartments but does not have a primary focus of inflammation is termed *panuveitis*. The onset of uveitis may be sudden or insidious, and the duration of the attack may be limited (≤ 3 months' duration) or persistent (> 3 months' duration). The course of uveitis is described as acute, recurrent, or chronic. Acute uveitis has a sudden onset with a limited duration, as in acute anterior uveitis (AAU) seen with seronegative spondyloarthritis. Recurrent uveitis describes a course of multiple attacks of sudden onset and limited duration alternating with periods of remission when the uveitis is inactive and the patient is not undergoing therapy for the disease. Chronic uveitis typically has an insidious onset and a persistent duration, such as chronic anterior uveitis (CAU) associated with juvenile idiopathic arthritis (JIA).^{1,2}

Patients with AAU typically have a red, painful, photophobic eye. Slit-lamp examination reveals inflammatory cells in the anterior chamber. These cells may be deposited on the posterior corneal endothelium and are called *keratic precipitates*. The cellular inflammation in the anterior chamber may be so severe that it produces a *hypopyon* or layering of inflammatory cells within the anterior chamber. Exudation of protein into the anterior chamber, known as *flare*, may also be seen and can be so marked that a fibrin clot forms in the anterior chamber. A complication of anterior uveitis is the formation of adhesions between the posterior iris and the anterior lens surface (posterior synechiae). Posterior synechiae may frequently persist

after the inflammation has settled (Fig. 34.2). Anterior uveitis may also lead to the development of peripheral anterior synechiae, or scar tissue that forms between the peripheral iris and the posterior cornea. The anterior synechiae may be so extensive that the drainage angle of the eye becomes blocked, which can cause an increase in intraocular pressure and secondary glaucoma. Typically, AAU affects one eye at a time, although uncommonly both eyes may be affected simultaneously. Even though only one eye is affected at a time, both eyes may suffer attacks, in which case the uveitis is termed *recurrent, unilateral alternating AAU*.^{1,2}

AAU is most commonly associated with seronegative spondyloarthritis.^{1,3} The estimated annual incidence of AAU is 8.2 new cases per 100,000 population.⁴ Approximately half of these patients will possess the HLA-B27 gene, and 60% will have a diagnosis of seronegative spondyloarthritis.^{3,5} Seronegative spondyloarthritis includes ankylosing spondylitis (AS), reactive arthritis, arthritis with inflammatory bowel disease (IBD), and psoriatic arthritis.^{1,3,5-13} AAU occurs in 25% to 40% of patients with AS.⁶⁻⁸ Conversely, studies of patients with AAU have reported that AS is present in 18% to 34%.^{1,8} AAU is said to occur in 5% to 20% of patients with reactive arthritis at the initial attack and in up to 50% of these patients at long-term follow-up.^{6,7,9} Of patients with arthritis related to IBD, those with AS associated with IBD appear to be at greatest risk for the development of AAU. Spondylitis occurs in 20% of patients with Crohn disease and in 10% to 15% of patients with ulcerative colitis.¹⁰ Approximately 50% to 70% of patients with spondylitis associated with IBD are HLA-B27 positive.^{10,12} Of the HLA-B27–positive patients with IBD, AAU will develop in 50%.^{5,10,12} Among patients with psoriatic arthritis, AAU occurs in approximately 7% to 10%.^{7,8,11,13} Although unilateral, alternating AAU is the most typical type of uveitis associated with seronegative spondyloarthritis, chronic and bilateral uveitis also occurs occasionally and may be seen more frequently in women with IBD or with psoriatic arthritis.^{7,11,12,14}

CAU is less frequent than AAU and may be seen with several disorders, most often sarcoidosis. The rheumatic disease most commonly associated with CAU is JIA.¹⁵ Approximately 12% to 17% of children with JIA have uveitis.^{15,16} A population-based study performed in Finland reported the mean annual incidence and prevalence rates for JIA-associated uveitis to be 0.2 and 2.4 cases per 100,000 population, respectively.¹⁷ Although recurrent AAU is seen with enthesitis-related arthritis, the HLA-B27–associated subgroup of JIA, CAU is more commonly associated with JIA and is seen with antinuclear antibody (ANA)-positive oligoarticular disease at frequencies reported to be approximately 30%.^{18,19} Even though CAU has traditionally been reported in patients with ANA-positive oligoarticular disease, one study suggested a similar frequency in those with ANA-positive polyarticular disease, thus suggesting that the presence of ANA and not the type of arthritis is the key risk factor for CAU.¹⁹ Although it has traditionally been said that cases of JIA-related CAU occur more frequently in girls, one retrospective study of 90 children with JIA found no gender difference in the risk for development of CAU.¹⁵ CAU tends to be insidious and minimally symptomatic (“white eye” uveitis; Fig. 34.3); therefore, it is recommended that patients with ANA-positive JIA be evaluated every 3 months in an effort to detect the uveitis early.²⁰ Two thirds of patients have bilateral disease, and in patients with unilateral disease, uveitis will develop in the other eye within 1 year of diagnosis in the majority.¹ The median time between the onset of arthritis and the development of uveitis has been estimated to be 2 years (range, simultaneous development to 10 years).¹⁶ Chronic uveitis typically requires long-term therapy. Although initial therapy typically consists of topical corticosteroids, increasingly, children with uveitis are treated with systemic agents such as methotrexate or biologics such as infliximab or adalimumab to control the disease.²¹⁻²⁵ A cross-sectional study of 2748 children with JIA demonstrated that approximately 75% had received a nonbiologic disease-modifying antirheumatic drug (DMARD), and the

Fig. 34.1 The structural elements of the eye that may be primarily involved in rheumatic disease processes are shown.

Fig. 34.2 Wide-beam slit-lamp view of "old" posterior synechiae (adhesions between the iris and lens) causing distortion of the pupil.

Fig. 34.3 Chronic uveitis in a patient with oligoarticular juvenile idiopathic arthritis: "white eye" uveitis.

presence of uveitis was strongly associated with use of a DMARD, both biologic and nonbiologic (e.g., methotrexate).²⁴

Sight-threatening ocular complications may develop in patients with CAU, with band keratopathy and cataracts each occurring in up to a third of patients.^{1,15,16,21-23,26-33} Secondary glaucoma occurs in 10% to 20% of patients with JIA-associated uveitis and is a poor prognostic finding.^{21-23,26-29} Posterior synechiae are common.^{21,22,28} Other complications include macular edema in 8% to 10% of cases and phthisis in 4% to 10%. Although blindness developed in 40% of patients reported in early series, more recent series have reported a better prognosis, with blindness occurring in about 10%.^{16,21-23,26,29} The improved prognosis appears to be due to earlier detection, better treatment, and better surgical management of the complications.^{28,30,32} Nevertheless, about 25% of patients with JIA-associated CAU will suffer some degree of visual impairment. Furthermore, because the uveitis may persist into adulthood, these children remain at risk for ocular complications from uveitis for decades.³³

Uveitis is a primary manifestation of Behçet disease.^{34,35} The uveitis in Behçet disease may be anterior uveitis (56% to 79% of cases, depending on the series), intermediate uveitis (18% to 66% of cases), posterior uveitis (3% to 29% of cases), or panuveitis with retinal vasculitis (29% to 41% of cases).^{1,34} The presence of retinal vasculitis confers a poor prognosis for vision and is described further in the later section "Retinal Vascular Disease." Anterior uveitis with or without hypopyon is the most common ocular finding in Behçet disease. Although studies from the 1960s and early 1970s reported hypopyon uveitis in up to 88% of patients, more recent studies have shown a decreased frequency of hypopyon to as low as 9%.^{1,34,36} This reported decrease probably represents earlier diagnosis and more aggressive therapy. The uveitis associated with Behçet disease is typically bilateral. In one series, 81% of patients had bilateral uveitis after 1 year and 93% by 2 years.³⁴⁻³⁷

Bilateral CAU may also occur with essential mixed cryoglobulinemia,³⁸ hypocomplementemic urticarial vasculitis syndrome (HUVS),³⁹ and familial juvenile systemic granulomatosis (FJSG).⁴⁰⁻⁴² Essential mixed cryoglobulinemia, or type II cryoglobulinemia, is a small-vessel vasculitis that may result in palpable purpura, arthralgias or arthritis, lymphadenopathy, hepatosplenomegaly, peripheral neuropathy, and hypocomplementemia.⁴³ Renal disease may also be seen in up to 60% of patients with essential mixed cryoglobulinemia.⁴³ Most cases of essential mixed cryoglobulinemia are associated with hepatitis C virus (HCV) infection, with an estimated 85% to 95% of patients having circulating antibodies to HCV.^{44,45} The diagnosis is made by the presence of cutaneous small-vessel vasculitis confirmed by biopsy and the presence of serum cryoglobulins in a patient with the typical clinical features.

An uncommon systemic small-vessel vasculitis, HUVS is characterized by recurrent urticarial lesions associated with cutaneous vasculitis, constitutional symptoms, arthralgias or arthritis, angioedema, and glomerulonephritis.⁴⁶ The joint and kidney disease may be indistinguishable from that found in systemic lupus erythematosus (SLE), and in fact, low ANA titers are often detected in patients with HUVS.⁴⁶ The diagnosis of HUVS is suggested in a patient with recurrent urticaria accompanied by leukocytoclastic vasculitis, constitutional symptoms, arthralgias, and hypocomplementemia. Continuous granular deposition of immunoreactants along the basement membrane zone seen on skin biopsy specimens via a direct immunofluorescence technique helps confirm the diagnosis.⁴⁷ Ocular findings have been reported in HUVS and include conjunctivitis, episcleritis, anterior uveitis, and diffuse anterior scleritis.^{46,47}

FJSG (www.omim.org/entry/186580), also known as *Jabs syndrome* or *Blau syndrome*, is an uncommon autosomal dominant genetic disease characterized by granulomatous polysynovitis, rash, vascular disease, and uveitis.⁴⁰⁻⁴² The syndrome is caused by mutations in the *NOD2* (*CARD15*) gene, which is involved in apoptosis. The uveitis associated with FJSG may be bilateral CAU,^{40,41} a chronic panuveitis with multifocal choroiditis.⁴² FJSG and CAU are often misdiagnosed as JIA or pediatric sarcoidosis. Patients may require aggressive medical therapy to control the uveitis, including immunosuppressive drugs.⁴² Ocular complications such as cataract and macular edema are common.⁴²

Management

Anterior uveitis usually responds to topically applied corticosteroids, which suppress the inflammatory response, and mydriatics, which prevent sequelae of the disease such as posterior synechiae. For the initial flare of uveitis, corticosteroid drops may be required on an hourly basis while awake. Topical corticosteroids have good penetration into the anterior chamber and are therefore useful in treating anterior uveitis. However, because they have limited penetration to the back of the eye, topical corticosteroids are

inadequate for intermediate or posterior uveitis. Periocular corticosteroid injections may provide high concentrations of corticosteroids in the eye and are useful in treating intermediate uveitis and cystoid macular edema, a common vision-threatening complication resulting from uveitis. For patients who do not tolerate periocular corticosteroid injections or if more sustained control of the uveitis is needed, oral corticosteroid therapy is used. Severe acute episodic uveitis may occasionally need treatment with a short course of oral prednisone in addition to intensive topical corticosteroids, as in the case of severe AAU. In patients with chronic posterior uveitis, panuveitis, or anterior uveitis unresponsive to topical corticosteroids, high-dose prednisone (e.g., 1 mg/kg/day) is administered until the inflammation is suppressed, followed by tapering to a lower dose. In many cases, long-term (low-dose) prednisone is needed to suppress the inflammation. If systemic corticosteroids are insufficient to control more severe forms of uveitis, immunosuppressive drug therapy may be required.^{1,34,48}

SCLERAL DISEASE

Scleral disease may be classified as episcleritis or scleritis. Episcleritis is associated with discomfort rather than pain, more superficial ocular inflammation, and less frequent ocular complications and typically has a less frequent association with systemic disease.⁴⁹ The clinical findings depend on whether only the episclera is involved or whether deeper tissue involvement is present. Episcleritis may be nodular or simple and is usually a self-limited condition that often resolves without treatment. Resolution of the inflammation may be expedited by the use of topical corticosteroids. In severe or recurrent cases, nonsteroidal antiinflammatory drugs (NSAIDs) have also been used. Slit-lamp examination is required to differentiate this condition from other causes of “red eye,” such as conjunctivitis and iritis.^{34,49-51}

Scleritis is often characterized by pain, deeper inflammation and edema in the sclera, and frequent ocular complications and is associated with an infectious or systemic disease in approximately 50% of cases.⁴⁹⁻⁵² Unlike episcleritis, which is typically self-limited and remits spontaneously, scleritis generally requires therapy. Scleritis may be classified as diffuse anterior, nodular anterior (Fig. 34.4), posterior, or necrotizing (Fig. 34.5). Scleromalacia perforans is a separate category with an insidious but destructive scleral process that is seen in patients with long-standing rheumatoid arthritis (RA). Any of the previously mentioned types of scleritis may be found in association with RA, although diffuse anterior scleritis is most common.⁴⁹

Approximately 10% of patients with scleritis will have an associated infection, such as syphilis, Lyme disease, or herpes zoster ophthalmicus.⁵⁰ Patients with scleritis appear to have a higher frequency of rheumatic disease.⁵³ Forty percent of patients with scleritis will have a rheumatic disease, the most frequent of which is RA.⁵⁰ Scleritis affects an estimated 1% to 6% of patients with RA and 14% of patients with rheumatoid vasculitis.^{50,54,55} Although estimates of the frequency of scleritis in patients with RA have been as high as 6%, large series have shown that approximately 1% of patients with RA have scleritis.^{49,53} Patients with RA and scleritis tend to have longer-duration and more severe disease and a higher prevalence of extraarticular disease.^{52,54,55} One study of patients with necrotizing scleritis or necrotizing keratitis and RA suggested increased mortality in these patients.⁵⁴

Fig. 34.4 Diffuse and nodular scleritis involving predominantly the upper temporal quadrant of the globe.

The second most frequent systemic disorder associated with scleritis is the systemic vasculitides (most commonly antineutrophilic cytoplasmic antibody [ANCA]-associated granulomatous vasculitis); other associated diseases include SLE, IBD, and relapsing polychondritis.⁴⁹⁻⁵² Any type of vasculitis may be present with scleritis, but half of cases of vasculitis-associated scleritis are due to ANCA-associated granulomatous vasculitis.⁵⁰ Furthermore, in half of patients with vasculitis and scleritis, the scleritis will be the initial feature of the disease.⁵⁰ Scleritis is common in ANCA-associated granulomatous vasculitis, in which it occurs in 16% to 38% of patients, and it is either the first or second most frequent ocular feature, depending on the series.^{34,55-58} The scleritis can be of any type, particularly diffuse anterior or necrotizing scleritis. Marginal corneal ulcers are often seen in association with the scleritis (necrotizing sclerokeratitis) and occasionally without scleritis (see the later section “Corneal Disease”).^{54,57} Posterior scleritis has also been reported.¹

All types of scleritis have been associated with IBD, including necrotizing scleritis and posterior scleritis.^{59,60} The scleral inflammation may parallel the activity of the underlying bowel disease.⁵⁹ Scleral involvement is the most common ocular manifestation of relapsing polychondritis and occurs in approximately 35% to 41% of patients.^{61,62} Most often, diffuse anterior scleritis is the type present, but recurrent episcleritis, necrotizing scleritis, or posterior scleritis may also be seen. An association between scleritis and AS and other forms of seronegative spondyloarthritis has been reported.⁵⁰

Management

Episcleritis can be treated by observation only or a short course of topical corticosteroids because the disease is usually self-limited. Scleritis typically requires systemic therapy and may call for treatment directed at controlling the underlying systemic disease, as in vasculitis.^{49-52,53,58} NSAIDs, particularly flurbiprofen and indomethacin, are effective in the initial management of anterior scleritis in approximately one third of patients.⁴⁹ If NSAID therapy fails to control the anterior scleritis or if posterior or necrotizing scleritis is present, oral prednisone therapy starting at 1 mg/kg/day (60 to 80 mg daily) is needed.^{48,49,63} For cases in which oral prednisone does not control the scleritis or when it cannot be tapered to an acceptably low daily dose, a steroid-sparing immunosuppressive agent may be required.^{48,49} Approximately one third of patients with scleritis require immunosuppressive drug therapy; historically, cyclophosphamide has been the drug used most often.^{49,63} Antimetabolites such as mycophenolate mofetil (CellCept) and biologics have also been reported to be effective.^{64,65} Necrotizing scleritis and scleritis with an underlying systemic vasculitis nearly always require immunosuppressive drug therapy.^{49-52,54,57,63} A standardized grading system has been advocated to help monitor patients during treatment.⁶⁶

RETINAL VASCULAR DISEASE

Ophthalmologists often use the term “retinal vasculitis” to encompass most retinal vascular inflammatory diseases regardless of whether true vasculitis is present. For purposes of this chapter, retinal vasculitis is defined as inflammation of the retinal vessels accompanied by intraocular inflammation and retinal vessel occlusion. Although most ophthalmologists do not distinguish among the different types of retinal vascular disease, we

Fig. 34.5 Necrotizing scleritis in a patient with severe rheumatoid arthritis.

Fig. 34.6 Fundus photographs from a patient with Behçet disease demonstrating retinal vasculitis. (a) Early macular lesion. (b) Progressive disease 1 month later. (From Thome JE, Jabs DA. *Rheumatic diseases*. In: Ryan SJ, editor. *The retina*. 4th ed. London: Elsevier; 2006, p. 1383-408.)

distinguish retinal vasculitis from the occlusive vasculopathies such as the antiphospholipid antibody syndrome associated with SLE (where no intraocular inflammation is present).

Retinal vasculitis may involve the retinal arteries, capillaries, or veins, and it may cause significant visual loss.^{67,68} Retinal vasculitis can be seen in the systemic vasculitides, but it is an uncommon complication except for Behçet disease, in which retinal vasculitis is the most frequent ocular complication in some series.^{34,67-70} In Behçet disease, inflammation may involve both veins and arteries and result in arterial occlusion and retinal necrosis (Fig. 34.6). Occasionally, secondary neovascularization and retinal detachment develop.⁶⁸⁻⁷⁰ The end stage of the disease is a blind, painful eye with secondary glaucoma, rubeosis, and retinal detachment. The natural history of ocular Behçet disease without treatment is poor. The majority of untreated patients will lose all or part of their vision within 5 years, with 74% of eyes in one series having vision worse than 20/200.⁶⁹ For eyes that deteriorated to no light perception, vision declined to this level over a period of 3.6 years.^{36,69} With treatment, clinical outcomes are improved but remain somewhat guarded, with the rate of any ocular complication estimated to be 0.45 per eye-year and rates of vision loss to the 20/200 level or worse being approximately 10% per eye-year.³⁵

Corticosteroid therapy appears to delay progression of the disease but does not alter the ultimate outcome, and therefore immunosuppressive drug therapy is used for the treatment of retinal vasculitis complicating Behçet disease.^{34,48} Initially, chlorambucil was used, typically at a dose of 0.1 to 0.2 mg/kg/day.^{48,71-77} Uncontrolled case series of chlorambucil therapy for Behçet disease have shown long-term, drug-free remissions after 2 years of treatment.^{49,71,72} Fewer published data are available for cyclophosphamide as treatment of ocular Behçet disease, but some clinicians have found it to be as effective as chlorambucil and easier to use.⁴⁹ Cyclosporine and azathioprine have also been reported to be effective in the treatment of ocular Behçet disease, and they have been shown to be efficacious in randomized clinical trials.^{49,75-78} However, nearly 25% of patients treated with azathioprine either had no benefit in terms of the frequency and severity of ocular attacks or required additional therapy, and only 50% of patients treated with cyclosporine had a good response.^{49,75,77,78} Studies of patients with ocular Behçet disease treated with infliximab (Remicade) have suggested that it may be effective, although the dose required appears to be 5 mg/kg/mo or higher.^{79,80}

Microvascular vasoocclusive disease can also affect the retinal vasculature. In SLE the retinal capillaries are involved and primarily result in cotton-wool spots or microinfarcts of the nerve fiber layer of the retina.⁸¹ The prevalence of retinopathy varies widely depending on the patient population studied, from 3% of ambulatory outpatients to 28% of hospitalized patients with SLE having retinal vascular findings.^{82,83} These findings occur in the absence of intraocular inflammation. More extensive retinal and vasoocclusive disease can occur with active SLE or as a result of antiphospholipid antibody syndrome (Fig. 34.7).⁸²⁻⁸⁴ This more severe retinal vasoocclusive disease occurs in less than 1% of patients with SLE, appears to be associated with central nervous system lupus,⁸³ and includes central retinal artery occlusion, central retinal vein occlusion, branch artery occlusion, and diffuse retinal vasoocclusive disease (Fig. 34.8).⁸⁴ With severe retinal vascular disease, the prognosis for vision is poor, and retinal neovascularization commonly develops. Even less common than retinopathy is lupus chorioidopathy (Fig. 34.9).⁸⁵ The clinical changes seen in patients with lupus chorioidopathy involve serous elevations of the retina, most often affecting the neurosensory retina, and serous elevations of the retinal pigment epithelium, and combined elevations may also be seen. These clinical findings

Fig. 34.7 Acute, severe, retinal vasoocclusive disease affecting the upper temporal retinal vessels. A large number of hemorrhages and white choroidal and retinal infiltrates are present.

Fig. 34.8 Fundus photograph demonstrating diffuse vasoocclusive disease in a patient with systemic lupus erythematosus. (From Jabs DA, Fine SL, Hochberg MC, et al. *Severe retinal vaso-occlusive disease in systemic lupus erythematosus*. *Arch Ophthalmol* 1986;104:558-63.)

are associated with a systemic vascular disease, either hypertension from lupus nephritis or systemic vasculitis.⁸⁵ Treatment of the underlying disease with systemic corticosteroids and immunosuppressive agents if needed and control of the hypertension can lead to resolution of the serous retinal detachments.⁸⁵

Central retinal artery occlusions can be seen in patients with giant cell arteritis (GCA), although ischemic optic neuropathy is a more classic finding (see later).^{34,67,68,86}

Arteriovenous anastomoses result from shunting of blood from artery to vein without an intervening capillary bed. They are seen commonly in the midperiphery of the retina in patients with Takayasu arteritis.^{1,34,87-89} The arteriovenous anastomoses can shunt blood away from the peripheral retina,

Fig. 34.9 Fundus photograph of a patient with choroidopathy and systemic lupus erythematosus. (From Jabs DA, Hanneken AM, Schachar AP, Fine SL. *Choroidopathy in systemic lupus erythematosus*. *Arch Ophthalmol* 1988;106:230-4.)

which occasionally leads to areas of retinal nonperfusion with subsequent neovascularization of the retina and vitreous hemorrhage.^{1,87-89}

OPTIC NERVE DISEASE

Optic nerve diseases associated with rheumatic disease include ischemic optic neuropathy and optic neuritis.³⁴ The characteristic features of ischemic optic neuropathy are painless sudden loss of vision, decreased color vision, and an altitudinal visual field defect. A relative afferent pupillary defect is present in the affected eye. The optic nerve head may be swollen (as found in anterior ischemic optic neuropathy) or may appear normal initially (as in retrobulbar optic neuropathy). The loss of visual acuity and visual fields is usually permanent, and the optic nerve head becomes atrophic and pale (e.g., optic nerve pallor) over time. In some cases of ischemic optic neuropathy, however, partial recovery of visual acuity has been noted after large doses of pulse intravenous corticosteroids (e.g., 1 g/day of methylprednisolone for 3 days).^{90,91} Although ischemic optic neuropathy may occur with any type of vasculitis, as well as with SLE,⁹² it is seen most commonly in patients with GCA.⁹³

Optic neuritis is characterized by acute or subacute visual loss associated with retrobulbar pain, especially with pain on movement of the affected eye. Examination of the eye reveals decreased vision, a relative afferent pupillary defect, decreased color vision, and visual field loss. The optic nerve head may be swollen or appear normal initially, depending on whether the optic neuritis is anterior or retrobulbar. Visual symptoms result from optic nerve demyelination. Unlike ischemic optic neuropathy, up to 95% of patients with optic neuritis have visual acuity of 20/40 or better 1 year after the event.³⁴ Optic neuritis is most typically associated with multiple sclerosis and responds to pulse intravenous corticosteroids with more rapid improvement of vision. Optic neuritis may also occur in SLE; such patients typically have a steroid-responsive, but also steroid-dependent process.¹

ORBITAL DISEASE

Orbital disease in patients with rheumatic disease may include primary inflammation of the orbital tissue (e.g., orbital pseudotumor or orbital inflammatory syndrome), inflammation of the extraocular muscles (e.g., orbital myositis), or contiguous spread of inflammation from the sinuses, which most typically occurs in ANCA-associated granulomatous vasculitis.⁹⁴⁻⁹⁶ The most common initial sign of orbital disease is proptosis or anterior displacement of the eye caused by a space-occupying lesion or inflammatory process. Associated symptoms and signs include pain, blurred vision, diplopia (double vision) as a result of restriction of eye movement, eyelid swelling, and displacement of the globe. In ANCA-associated granulomatous vasculitis, orbital involvement is common and occurs in 15% to 50% of patients, and in some series it is the most common form of ophthalmic involvement.⁹⁴⁻⁹⁶ Orbital disease may be an extension of granulomatous inflammation from the sinus into the orbit. Such inflammation can lead to compartment syndrome within the orbit, proptosis, orbital apex syndrome, compressive optic neuropathy, and subsequent irreversible visual loss. Orbital pseudotumor separate from the sinus inflammation may also be seen.^{95,96}

Fig. 34.10 Active corneal ulceration with corneal infiltrates at the "leading edge" of an ulcer and associated conjunctival injection.

Systemic corticosteroids or immunosuppressive drug therapy aimed at controlling the underlying disease can decrease the proptosis, improve mobility, and reduce the associated symptoms, as well as improve visual acuity. Rarely, orbital decompression may be necessary if the inflammatory process has caused proptosis severe enough to compromise the optic nerve (orbital apex syndrome). The orbital disease accompanying ANCA-associated granulomatous vasculitis typically requires immunosuppression and may be difficult to control.

CORNEAL DISEASE

Corneal manifestations of rheumatologic disease include forms of keratitis (inflammation in the cornea) and dry eye disease, or keratoconjunctivitis sicca (KCS; described in the next section). Keratitis is classified as interstitial keratitis (IK) or peripheral ulcerative keratitis (PUK). The diagnosis of IK includes diffuse stromal keratitis, sclerosing keratitis, and deep keratitis. PUK is also known as *marginal keratitis*, *marginal corneal ulceration*, or *limbal guttering*. Limbal vasculitis may also be seen as a rare manifestation and is not discussed further here. Keratitis may occur on its own or in association with scleritis, in which case it is termed *sclerokeratitis*. Although PUK and sclerokeratitis are often associated with rheumatic disease, infectious causes such as herpes simplex and syphilis also need to be considered.

IK is characterized by nonsuppurative inflammation, usually with vascularization of the corneal stroma. It is generally caused by an immunologic response to an infectious agent (e.g., syphilis) but occasionally occurs in systemic disease, with the most common etiology being Cogan syndrome.⁹⁷ It may also occur as a common corneal complication of scleritis.^{49,50,62} The pericorneal or limbal inflammation is accompanied by peripheral corneal vessels that advance across the central cornea preceded by superficial stromal opacities. In nodular scleritis the corneal involvement may be restricted to one segment, but in diffuse scleritis the entire cornea may be involved, with a dense corneal leukoma being produced. Symptoms of IK include pain, tearing, photophobia, and conjunctival injection. The IK associated with Cogan syndrome typically responds to topical corticosteroid therapy.

Clinically, PUK is typically manifested as pain, though not always. Peripheral corneal infiltrates may develop. Epithelial breakdown of the cornea occurs, followed by corneal ulceration and stromal thinning, which may progress circumferentially and then centrally (Fig. 34.10).⁹⁸⁻¹⁰⁰ If left untreated, the lesion progresses and results in corneal perforation and loss of vision. Bacterial corneal infection must be excluded first, particularly in patients with compromised corneal epithelia (e.g., KCS secondary to Sjögren syndrome). PUK typically occurs in RA and often involves the lower half of the cornea in a furrowing of the corneal periphery (Fig. 34.11). The development of PUK in patients with RA has been linked to immunologically mediated small-vessel vasculitis of the pericorneal vessels and is associated with advanced RA, elevated rheumatoid factor titers, and increased risk for mortality.⁵⁴ PUK has also been reported to occur in patients with other connective tissue disorders such as ANCA-associated granulomatous vasculitis, relapsing polychondritis, SLE, and progressive systemic sclerosis.³⁴

Treatment of PUK is aimed at the underlying disease. Local therapy such as the use of cyanoacrylate adhesive glue and corneal or scleral patch grafts is often needed to prevent perforation and to maintain tectonic support of the globe.^{99,101-103} However, these measures will eventually fail if the

Fig. 34.11 Marginal ulceration of the cornea.

Fig. 34.12 Keratoconjunctivitis sicca.

underlying inflammation is not controlled. Very small central corneal perforations (<1.5 mm in diameter) may be sealed with a tissue adhesive such as cyanoacrylate glue. Larger perforations usually require emergency keratoplasty if any useful vision is to be salvaged. Topical corticosteroids are generally ineffective in the treatment of PUK and may accelerate the corneal thinning and increase the risk for corneal perforation.^{99,100}

KERATOCONJUNCTIVITIS SICCA

A common ocular complication of rheumatologic disease is KCS, or dry eye syndrome. Symptoms of KCS include dryness, ocular irritation, foreign body sensation, photophobia, and rarely pain. Sometimes patients complain of excessive tearing, which may merely describe a sensation or may be real and occur as a result of tear spillover. Clinically, the eyes may appear minimally affected with loss of surface luster, mild conjunctival redness, and perhaps some accumulation of mucus at the medial canthus (Fig. 34.12). Conjunctival and corneal punctate erosions occur secondary to failure of aqueous tear secretion and chronic damage to the oil-secreting glands of the palpebral conjunctiva, which induces more rapid evaporation of tears from the ocular surface. In severe cases, discrete corneal filaments may develop (filamentary keratitis), which represent tags of exfoliated epithelium still attached at one end and intermixed with surface mucin. Patients with KCS are more vulnerable to bouts of recurrent infectious conjunctivitis, perhaps as a result of reduced antibacterial tear lysozyme and lactoferrin. Thus, corneal ulcer and perforation are more likely to develop in these patients.

The diagnosis of KCS is made by a Schirmer test showing decreased tear production (typically <5 mm of wetting at 5 minutes in an anesthetized eye) and by demonstrating damage to the ocular surface with rose Bengal staining. The presence of KCS in association with evidence of salivary gland dysfunction, such as a positive minor salivary gland biopsy result or abnormal salivary flow study, as well as the presence of a defined connective tissue disease such as rheumatoid arthritis, SLE, or scleroderma, constitutes Sjögren syndrome (see Chapter 138).¹⁰⁴ Secondary Sjögren syndrome is diagnosed when a defined connective tissue disease is present and primary Sjögren syndrome when no definable connective tissue disease is present. Sjögren syndrome affects approximately 11% to 13% of patients with RA and approximately 20% of patients with SLE.¹ The cause of the dry eyes and dry mouth in patients with Sjögren syndrome is glandular destruction and dysfunction as a result of a chronic lymphocytic and mononuclear inflammatory infiltrate of the lacrimal and salivary glands.¹⁰⁴⁻¹⁰⁶ Immunohistologic studies have suggested that most cells in this infiltrate are CD4+ T cells, with lesser numbers of CD8+ T cells and B cells.¹⁰⁶

Treatment of KCS includes tear replacement therapy with artificial tears, punctal occlusion, effective treatment of secondary lid disease such as blepharitis, and the use of topical cyclosporine eye drops. Topical cyclosporine appears to benefit patients with severe dry eye secondary to Sjögren syndrome by improving tear film break-up times and decreasing rose Bengal staining of the corneal surface.^{107,108} It has been suggested that the mode of action for topical cyclosporine may be decreased inflammation of the lacrimal gland leading to improved lacrimal gland function and an increase in tear production.¹⁰⁷

The heart in rheumatic disease

■ J. GERRY COGLAN ■ BENJAMIN SCHREIBER ■ DAVID P. D'CRUZ

- Cardiac complications are prevalent in rheumatic diseases; although any cardiac disease may occur, screening programs should focus on the most common associations.
- The presentation of cardiac disorders in rheumatic diseases is often atypical, and a high index of suspicion is required.
- A high prevalence of coronary disease is present in most patients with inflammatory rheumatologic conditions.
- Optimal management of atherosclerotic risk factors requires a proactive approach in rheumatology services.

OVERVIEW

Like all organs, the heart has abundant connective tissue; hence rheumatologic conditions can lead to abnormalities in all parts of the heart. Indeed, to summarize the cardiac pathologic conditions associated with connective tissue diseases (CTD) is to provide an overview of virtually all cardiac disorders. CTD may result in coronary artery disease, hypertension, cardiac failure, pericarditis, myocarditis, valvular heart disease, arrhythmias, and right-sided heart abnormalities either directly or secondary to pulmonary hypertension.

To begin, Table 35.1 shows the typical associations of various rheumatologic conditions with common cardiac disorders. This table is not intended to be exhaustive but rather to give a sample of the types of conditions one might consider in a given CTD population. Thus, for example, Behçet syndrome has been associated with pericarditis, myocarditis, endocarditis, intracardiac thrombosis, venous thrombosis, aortic and coronary aneurysms, and the more typical pulmonary artery aneurysms.

Patients with specific rheumatologic diagnoses should be monitored with particular cardiac complications in mind. Thus patients with rheumatoid arthritis (RA) are significantly more likely to develop coronary disease.¹ This statement is supported not merely by an excess of events but also by a threefold excess of coronary artery calcification.² In most patients symptoms of coronary atheroma are noted because of progressive exercise limitation. Given the confounding factors that limit mobility in RA, it is unsurprising that coronary disease often presents atypically in this population; hence the rheumatologist needs to be especially vigilant if such cases are to be identified before serious complications occur.

Systemic hypertension is common in the general population and has been reported as even more common in RA,³ although not all studies support this conclusion.⁴ However, recent studies confirm an increased prevalence of the typical complications of hypertension in RA patients, namely stroke and atrial fibrillation⁵; thus identification and treatment should be part of routine practice in the rheumatologic practice. Less clinically obvious associations include an increased incidence of heart failure, which may or may not relate to the fact that up to 30% of RA patients are found have cardiac amyloid in some postmortem studies.⁶ Finally, although it is rare, some patients develop hydroxychloroquine cardiomyopathy, a form of lysosomal storage disorder that may present with heart failure but is diagnosable only on cardiac biopsy.⁷

Libman-Sacks endocarditis as seen in lupus is by now rather rare except as an echocardiographic abnormality.⁸ Pericarditis, by contrast, occurs frequently but only uncommonly as part of the index event, and even then it is part of a multisystem presentation⁹; thus the cardiologist rarely has to

consider lupus as part of the differential when assessing the typical patient with viral pericarditis. The association of lupus with ischemic heart disease (IHD) is not well recognized outside rheumatology circles. As with RA the association is driven by promotion of atheroma, because coronary calcification is much more common at a given age in the systemic lupus erythematosus (SLE) population.¹⁰ In young women who experience coronary events, SLE is the most likely driver after diabetes and familial hypercholesterolemia.¹¹ Other associations, such as congenital complete heart block, are sufficiently understood that specific advice can be given to patients who possess the appropriate antibodies.¹² On the other hand, pulmonary arterial hypertension (PAH) is somewhat less common than the literature would suggest and is rather remarkable for showing an excellent response to immunosuppressive therapy and available pulmonary vasodilators.¹³

Systemic sclerosis (SSc) is now recognized as the third most common cause of PAH after idiopathic and congenital heart disease.¹⁴ Pulmonary hypertension related to lung disease and heart failure is also prevalent in SSc patients.¹⁵ Midwall fibrosis in a noncoronary distribution on cardiac magnetic resonance imaging (CMR) has been labeled as *scleroderma cardiomyopathy*¹⁶; however, such abnormalities are now understood to be nondiagnostic (they are present in cardiomyopathy of other causes) and are among the less common CMR abnormalities associated with scleroderma.¹⁷ The cardiac manifestations are thus protean: troponin-positive cardiomyopathy associated with myositis overlap, troponin-negative progressive dilated cardiomyopathy, and diastolic dysfunction associated with hypertension or replacement fibrosis, as well as a high prevalence of conduction tissue disease.¹⁸

The medium-vessel vasculitides form a spectrum of disorders, ranging from coronary artery aneurysms (polyarteritis nodosa), to intramyocardial vasculopathy presenting as dilated cardiomyopathy, to eosinophil-associated endomyocardial fibrosis.¹⁹

Dermatomyositis and polymyositis and scleroderma with myositis overlap, leading to troponin-positive myocarditis that, unchecked, results in dilated cardiomyopathy associated with midwall fibrosis on CMR.²⁰ Of note, steroids that may ease the skeletal myositis may be insufficient to prevent the progression of the cardiac element; this may require more robust immunosuppression.²¹ Less recognized is the fact that in common with other inflammatory CTDs these conditions are associated with atherosclerosis.²²

The classic large-vessel vasculitides are typically associated with stenosis and aneurysms of the aorta and its major branches in the case of Takayasu arteritis, and the coronary arteries in Kawasaki disease. All may involve the coronary arteries—in particular, the coronary ostia may be involved in Takayasu arteritis, whereas coronary artery aneurysms may occur in Behçet syndrome.²³

Sarcoid is feared as a cause of sudden death related to myocarditis and midwall fibrosis²⁴ but should perhaps be recognized as an important cause of pulmonary hypertension,²⁵ associated primarily with lung disease but also secondary to cardiac failure—primarily diastolic or, at the extreme end, a restrictive pattern—and occasionally related to pulmonary arterial involvement.

With this overview as a backdrop, various cardiac pathologic conditions and the role of associated rheumatologic disorders are now considered.

CORONARY ARTERY DISEASE

The prevalence rate of diagnosed IHD in 60-year-old men is 11%, whereas in 60-year-old women it is 3.5%.²⁶ Thus, although inflammatory conditions such as RA are associated with a 50% increase in risk, the low prevalence of CTDs means that 99.5% of all coronary artery disease (CAD) is not causally related to CTD. Hence, looking for the contribution of CTD to CAD in

TABLE 35.1
Typical associations of various rheumatologic conditions with common cardiac disorders

Rheumatologic diagnosis	Most prevalent	Others
Rheumatoid arthritis	IHD (+50%) Hypertension (+40%)	Cardiac amyloid, hydroxychloroquine cardiomyopathy
Lupus	Pericarditis: (30%) Premature IHD (×50)	Congenital complete heart block, PAH, valve lesions
Systemic sclerosis (SSc)	PAH, SSc cardiomyopathy	Pericardial effusion, conduction abnormalities
Polyarteritis nodosa, Churg-Strauss syndrome, Wegener granulomatosis	Cardiac failure (microvasculopathy)	Endomyocardial fibrosis (Churg-Strauss syndrome)
Dermatomyositis/polymyositis	IHD (×2)	Myocarditis
Takayasu arteritis, Behçet syndrome, Kawasaki disease	Vascular aneurysms or stenoses	Hypertension, bruits (Takayasu arteritis), pulmonary artery aneurysm (Behçet syndrome)
Giant cell arteritis, polymyalgia rheumatica	Medium-vessel vasculitis	Aortic aneurysm/dissection, stenoses
Sarcoid	Sudden cardiac death, pulmonary hypertension	Subclinical myocarditis

IHD, ischemic heart disease; PAH, pulmonary arterial hypertension.

BOX 35.1 CONTRIBUTION OF RHEUMATOID ARTHRITIS TO CORONARY ARTERY DISEASE

Prevalence of CAD = 3.5%; prevalence of RA = 1%; prevalence of CAD + RA = (3.5% of 1% × 3/2) = 0.0525%.

Excess CAD related to RA = 0.0175% = 1/200 of all CAD.

CAD, coronary artery disease; RA, rheumatoid arthritis.

the cardiology setting is futile. By contrast, the impact within a rheumatology cohort may be dramatic. Box 35.1 shows how the figures are derived.

The excess of coronary disease in inflammatory arthropathies is well documented. In a meta-analysis of 24 studies in RA populations conducted before 2005, Avina-Zubieta and colleagues¹ found a relative risk of 1.5 (95% confidence interval, 1.4 to 1.6) for cardiac death, 1.59 for diagnosed IHD, and 1.52 for cardiovascular disease in 117,000 patients. These were mainly noninception studies, however, with no analysis of risk factor prevalence. In an inception study, Crownson and associates²⁷ followed 525 patients over 8 years and observed that the standard Framingham risk score underestimated the cardiac event rate in the RA population by half for those younger than 65 years and by two thirds for those older than 75 years, which demonstrates that the relationship is not fully explained by standard risk factors. In a study of coronary calcification, a risk ratio of 3.4 was observed in RA patients compared with control subjects.²

In lupus a similar pattern of excess of coronary calcification after correction for age and sex has been identified.¹⁰ The relative risk of coronary events is much higher than anticipated even allowing for this, especially in young women, which suggests a much more direct causative relationship between the inflammatory and prothrombotic disorders.¹¹ Excess coronary events have also been identified in dermatomyositis, polymyositis, and the seronegative arthropathies.²² By contrast, no excess is seen in patients with scleroderma, which suggests that there is merit in fully understanding the dominant drivers for atherosclerosis and thrombosis in different rheumatologic conditions.²⁸

Better understanding of the relevant factors inducing inflammation and their correlation with coronary calcification could lead to improved insights into atherosclerosis, and greater understanding of the prothrombotic drivers may help unravel the relative importance of platelet activation compared with aspects of the clotting cascade.

Prevention of coronary events in rheumatologic conditions

Very large, long-term, placebo-controlled studies in the general population have shown that statin therapy is effective in secondary and primary prevention. Likewise, huge carefully constructed observational studies have provided a solid base for advising smoking cessation in the prevention of

coronary disease. Although the role of diet remains pivotal, evidence supporting effective intervention remains largely observational.

Intuitively, when one is deciding whether or not to treat to reduce conventional risk factors, one would recommend avoiding cyclooxygenase-2 inhibitors and steroids, and instead advocate widespread use of disease-modifying antirheumatic drugs and risk modification to reduce Framingham risk score given the known excess of coronary disease in certain rheumatologic conditions.

The only randomized, double-blind trial of statin therapy in RA was the Trial of Atorvastatin in Rheumatoid Arthritis (TARA), a 6-month trial involving 110 subjects. This study demonstrated that atorvastatin was safe and reduced cholesterol levels; secondary observations included a reduction of disease activity as well as interleukin-6 (IL-6) and C-reactive protein (CRP) levels.²⁹ A large randomized, controlled trial in which 4000 patients with active RA were to receive either atorvastatin 40 mg or placebo (Trial of Atorvastatin for the Primary Prevention of Cardiovascular Events in Patients with Rheumatoid Arthritis [TRACE RA]) was terminated prematurely after having recruited 3000 patients; the decision to terminate was due to the low rate of cardiac events in the placebo group.³⁰

A randomized, placebo-controlled trial with 2-year follow-up examined treatment with atorvastatin 40 mg daily in 200 SLE patients. At baseline 43% of patients had coronary artery calcification; there was no significant difference between the atorvastatin-treated and placebo-treated groups in progression of coronary artery calcification, carotid intima media thickness, or carotid plaque.¹⁰ An assessment of the feasibility of a prevention trial at a lupus clinic showed that fewer than 6% of the population would enter a primary prevention study, with over half receiving disqualifying medicines, one in three not in clinically stable condition or perceiving themselves as already taking too many tablets, and one in five refusing to participate in clinical trials.³¹

Despite such obstacles there is a clear clinical need. An assessment for the predictors of coronary events in a population of RA patients showed that traditional risk factors (diabetes, hypertension, and high triglycerides) and evidence of disease activity (elevated erythrocyte sedimentation rate and CRP level after 6 months of therapy) independently predict events.³² The Framingham risk score does predict coronary events, although it underestimates the event rate by more than half.²⁷ This suggests that to reduce coronary events in RA one should screen for traditional risk factors and consider therapy at much lower levels of calculated risk, similar to the way one assesses diabetic patients. In addition one may deduce that excellent control of disease activity may be beneficial not just in preventing complications but also in reducing coronary events.

The lack of evidence to support such deductions probably explains the poor compliance with guidance advice. In their assessment of coronary risk factor management at a lupus clinic Demas and colleagues³³ found that fewer than 3% of patients had had all five coronary risk factors assessed within the preceding year, and only a quarter had had four of five recommended assessments performed.

Antiphospholipid syndrome is rather different from the other inflammatory autoimmune diseases in that it is associated with arterial and venous thrombosis. Several studies have shown that thrombotic CAD can lead to

myocardial infarction, although this is less common than venous thrombosis (3% of 1000 patients with antiphospholipid syndrome experienced myocardial infarction, whereas 32% of patients had deep vein thrombosis).³⁴

In the systemic vasculitides, especially antineutrophil cytoplasmic antibody-associated diseases such as granulomatosis with polyangiitis (Wegener granulomatosis) and microscopic polyangiitis, there is an excess of deaths due to cardiovascular causes, but data from the large prospective treatment trials that recorded cause of death have not yet been published.

Many attempts have been made to treat inflammation directly; none has been successful, but these attempts have led to a better understanding of the drivers of inflammation in atherosclerosis. Increased CRP and IL-6 levels, although strongly associated with inflammation and predictive of event rates, are probably not the drivers of atherosclerosis. By contrast, myeloperoxidase levels directly promote atherogenesis in animal models and have a strong claim on relevance based on human studies.

ATYPICAL CORONARY DISEASE IN CONNECTIVE TISSUE DISEASE

The classic CTD associated with specific coronary lesions is Kawasaki disease or mucocutaneous lymphadenopathy.³⁵ This condition classically affects male children younger than 5 years of age but recently has been reported in adults without the classical dermatologic lesions.³⁶ Administration of intravenous immunoglobulin IVIG while the disease is active reduced the prevalence of coronary aneurysms from 20% to 5%.³⁵ The aneurysms typically involve the proximal coronary arteries with substantial surrounding inflammatory tissue during the acute phase and can usually be identified on echocardiography.³⁵ Later, thin-walled aneurysms and secondary stenotic lesions predominate, and a significant body of experience now indicates that stenting of these lesions is safe and practical.³⁷

Behçet syndrome, although causing primarily dilation of pulmonary vessels, possibly through inflammation of the vasa vasorum (Fig. 35.1), also is associated with coronary aneurysms, which again develop in association with obvious disease activity and are improved by immunosuppressive therapy.³⁸ Although Takayasu arteritis generally spares vessels as small as the coronaries, involvement of the coronary ostia in aortic disease is well documented and causes angina and heart failure.¹⁹

Fig. 35.1 Pulmonary artery aneurysm shown on computed tomographic pulmonary angiogram in a patient with Behçet syndrome and pulmonary hypertension.

Although coronary artery aneurysms are rare, atherosclerotic and congenital aneurysms are much more prevalent than CTD-associated aneurysms.³⁹

CORONARY ARTERITIS

Intramyocardial coronary arteritis occurs in conditions such as Churg-Strauss syndrome, granulomatosis with polyangiitis, and polyarteritis nodosa,¹⁹ although the latter can also cause coronary artery aneurysms.³⁹ Involvement of the coronary vessels causes no immediate symptoms and generally emerges as a clinical problem only when cardiac failure ensues.¹⁹ The natural history is not resolved because the disorder is subclinical, but the prevalence of heart failure (the end result) appears to decrease with good control of disease activity.⁴⁰

FUNCTIONAL CORONARY ARTERY DISORDERS

SSc is thought to impair intramyocardial vascular tone, leading to ischemia-reperfusion injury, and the classical histologic lesions of contraction band necrosis and replacement fibrosis are typical of reperfusion injury.¹⁸ Difficulty arises in determining the role of such observations in clinical disease, which is much less common than the histologic findings might suggest, and comparative histologic studies indicate that such lesions are only modestly more common in SSc patients than in the normal population.¹⁸

HYPERTENSION

Inflammation is thought to play a key role in the pathogenesis of hypertension. In prospective studies higher CRP levels are predictive of subsequent development of hypertension. After correction for confounders, however, a causative association seems highly unlikely.⁴¹ Early work shows many other associations, for example, between levels of fibrinogen, α_1 -antitrypsin, haptoglobin, ceruloplasmin, and orosomucoid and future hypertension,⁴² as well as between serum levels of soluble tumor necrosis factor receptors, IL-6, and IL-1 receptor antagonist and end-organ damage in the form of left ventricular (LV) hypertrophy.⁴³ Although by no means conclusive, such observations support findings in many animal models of hypertension. Idiopathic hypertension has to date defied a unifying theory of causation. Among the front runners presently is the theory of intrarenal microvascular endothelial dysfunction leading to transient microtubular ischemia.⁴⁴ In susceptible individuals secondary inflammation leads to persistent ischemia and thus chronic renin-angiotensin system activation.⁴⁴

Endothelial dysfunction is a hallmark of CTD, as is a heightened inflammatory response; thus a milieu is created in which an increased prevalence of systemic hypertension may well be expected. This is in addition to specific disorders such as direct renal involvement in SSc¹⁵ and lupus renal involvement, salt retention and hypertension induced by nonsteroidal anti-inflammatory drugs (NSAIDs)⁴⁵ or steroid therapy, and of course aortic and renal vascular stenosis in the large-vessel vasculitides.¹⁹

Antiphospholipid syndrome is associated with both renal thrombotic microangiopathy and stenotic lesions of the renal arteries, likely due to intimal hyperplasia, resulting in labile hypertension.⁴⁶

Among rheumatologic conditions, gout and hyperuricemia have the strongest association with hypertension.⁴⁷ In *in vitro* studies uric acid is a powerful pro-oxidant in the intracellular environment,⁴⁸ causing endothelial dysfunction⁴⁹ and inflammation. In humans, intervention to reduce uric acid levels appears to ameliorate hypertension.⁵⁰ Although the role of uric acid in hypertension remains a matter of controversy, there is a strong evidence base indicating that such a role is real and can contribute to our understanding of the nature of hypertension.

The association between psoriasis and multiple risk factors for cardiovascular disease, including hypertension, hyperlipidemia, diabetes, and metabolic syndrome, is well established. Increased levels of IL-6 and proinflammatory cytokines⁵¹ provides one possible explanation, and confounding factors such as treatment effects (e.g., cyclosporine) have not been excluded.

One would anticipate that hypertension is demonstrably more common in RA; however, a meta-analysis of available case-control studies showed no such excess in 2956 patients and 3713 controls,⁴ although results of individual studies are suggestive of an excess, particularly in those with significant long-term steroid exposure.³ More intriguingly, the typical consequences of hypertension, atrial fibrillation and stroke, have been found to be significantly more common in RA.⁵ This study included over 4 million adults older than age of 18 plus over 18,000 patients with RA followed for more than

13 years, and demonstrated a 40% excess of atrial fibrillation at all ages and a 30% excess of stroke that increased with age.

In other conditions such as lupus and scleroderma, renal involvement and low prevalence add considerably to the complexity of demonstrating a link between the underlying inflammatory drivers and hypertension.

HEART FAILURE AND DIRECT MYOCARDIAL INVOLVEMENT

Heart failure as a syndrome resulting from coronary disease, hypertension, myocardial disease, and valvular disease is expected as a consequence of rheumatologic diseases. In heart failure clinics atherosclerotic coronary disease dominates, so one might anticipate that conditions such as RA would lead to infarction-related heart failure—yet this is uncommon. With rarer diseases such as lupus, heart failure due to direct cardiac or valve involvement is classically described. Yet sarcoid is probably the dominant reason why cardiologists become involved in treatment of rheumatologic conditions.

RA is associated with a greater relative risk of heart failure (2:1), mainly diastolic. Proposed causes include amyloidosis, NSAID use, glucocorticoid therapy, IHD, and direct myocardial involvement.⁶ The presentation of heart failure is subtle (preserved systolic function), and heart failure is associated with a worse prognosis in the 6 months following acute exacerbations.⁵²

From the rheumatologic perspective, the salient points are that echocardiography is relatively insensitive as a tool for diagnosing RA-associated heart failure (assessment of diastolic dysfunction lacks specificity), and angiotensin-converting enzyme inhibition and β -blockade are not beneficial. Diagnosis requires a high index of suspicion, and measurement of brain natriuretic peptide (BNP) or N-terminal pro-brain natriuretic peptide (NT-proBNP) should be considered when heart failure is suspected. On echocardiography, an enlarged left atrium may be the only feature (and this can also be caused by prolonged atrial fibrillation). CMR may well prove useful in the future, but presently data are limited.

Cardiac failure should be very common in scleroderma—up to 70% of patients have histologic evidence of cardiac involvement on postmortem examination¹⁸ and a similar percentage exhibit abnormalities on CMR.¹⁷ However, clinically systolic LV dysfunction is rather uncommon,¹⁶ and diastolic heart failure is encountered in only a minority. Although systolic heart failure is seen occasionally in the context of renal crisis or in association with myocarditis,⁵³ most commonly cardiac involvement remains subclinical unless there is an associated cardiac stress. Right-sided heart failure secondary to pulmonary hypertension is the most common reason that scleroderma patients have symptoms and signs of heart failure. Whether the subclinical cardiomyopathy contributes to the frequency of right-sided heart failure in scleroderma remains a matter of speculation. It is clear that the right side of the heart fails despite facing lower pulmonary pressures than in idiopathic PAH.⁵⁴

Cardiologists are sensitized to the possibility of sarcoid cardiac involvement—not so much because of the occurrence of heart failure, but because of the association with sudden death and heart block. Nevertheless, a byproduct of this is an awareness of the possibility of sarcoid as an underlying diagnosis when a patient has myocarditis or restrictive cardiomyopathy. The prevalence of cardiac involvement in sarcoid depends on the series chosen. Postmortem series, which are inevitably biased toward overestimation, suggest that 30% of patients have granulomas in the heart and that premortem diagnosis is uncommon.⁵⁵ Clinical prevalence lies between 5%⁵⁶ and 40%.⁵⁷ The clinical relevance of abnormalities identified in screened populations varies from benign⁵⁸ to more than a 50% rate of death or need for device implantation in less than 2 years.²⁴

In sarcoid, steroid therapy appears effective in reducing the cardiac contribution to death.⁵⁷ CMR is thought to be particularly sensitive in identifying sarcoid cardiac disease, and estimates of prevalence are likely to change as this technique is used more frequently.⁵⁸

Heart failure may present as part of an active inflammatory myocarditis, with persistent troponin leakage and evidence of diffuse myocardial edema and midwall fibrosis on CMR. Steroids and occasionally more aggressive immunosuppression (such as mycophenolate) is the mainstay of therapy. Therapy should be initiated early to avoid reduction of the ejection fraction to less than 40%, and given the association with ventricular arrhythmias, consideration should be given to use of a life vest or implantation of a defibrillator to deal with unpredictable arrhythmias during the initial phase of therapy.^{57,24} Alternatively, patients may have heart failure of more insidious onset, often associated with very large atria and features of restriction. This is a difficult form of heart failure to treat; only diuretics appear to have any role in management.

Fig. 35.2 Extensive diffuse myocardial edema in a patient with sarcoid-associated acute myocarditis. Cardiac magnetic resonance image showing late gadolinium enhancement (mottled gray appearance of left ventricular myocardium).

Eosinophilic endomyocardial fibrosis is almost never found in patients with Churg-Strauss syndrome and cardiac symptoms. Rather, a more common presentation in these patients is dilated cardiomyopathy thought to be due to microvascular ischemia, a process that is not necessarily controlled with standard immunosuppressive therapy for the systemic condition. An alternate possible explanation is suggested by recent data from a registry of 49 patients with Churg-Strauss syndrome. Nearly half of these patients had evidence of cardiac involvement, and in over a quarter¹³ this took the form of endomyocarditis on biopsy; these patients had the worst outcome.⁵⁹ Once heart failure is present, standard therapy is appropriate; however, prevention theoretically should now be possible by monitoring troponin levels when treating patients with these conditions if there are any concerns about cardiac involvement.

Current teaching is that heart failure in SLE is most likely the result of standard dilated cardiomyopathy or coronary disease rather than direct lupus or antimalarial drug toxicity.⁶⁰ Certainly, given the increased frequency of coronary disease, computed tomographic angiography seems a sensible first investigation in patients with systolic heart failure.¹⁰ CMR often shows evidence of myocardial edema and late gadolinium enhancement (Fig. 35.2), but whether this differentiates myocarditis from hydroxychloroquine toxicity has not been established, and myocardial biopsy with electron microscopic evaluation for myeloid bodies⁷ should be considered if other clinical features of disease activity are absent.

Heart failure is thought to be rare in inflammatory myopathies; however, the paucity of adequate registry data makes this uncertain. The finding of subclinical myocardial involvement in autopsy studies, backed by suggestions of a high cardiac mortality, indicate that cardiac failure may be underdiagnosed. Available data suggest that a process of lymphocytic infiltration similar to that observed in the skeletal muscle may affect the heart and that cardiac lesions may progress despite steroid therapy.²⁰ With more widespread use of troponin and NT-proBNP testing as well as CMR, the picture should clarify in the coming decade.

VALVULAR HEART DISEASE

Ask cardiologists about rheumatologic conditions that cause valvular heart disease, and they will recall Libman-Sacks endocarditis as a matter of historical interest and offer ankylosing spondylitis as a contributor to aortic valve disease. Such impressions are in part testament to the efficacy of current management of CTDs and in part reflection of cardiologic disinterest in subclinical valvular lesions.

Although clinically overt valve disease is now rare in SLE, echocardiographic studies suggest that involvement remains common, with 40% of patients exhibiting minor abnormalities on transthoracic echocardiographic and 70% on transesophageal echocardiographic studies, including vegetations in over 30%.⁸ Valvulitic lesions identified on transesophageal

echocardiography have been reported to exhibit activity in terms of progression and regression. Although a causative relation has not been demonstrated, a correlation between valvular lesions and stroke has been found, with microembolization proposed as a mechanism.⁶¹ It is increasingly recognized that the presence of antiphospholipid antibodies in SLE patients is more likely to be associated with cardiac valve disease than with Libman-Sacks endocarditis.⁶²

In ankylosing spondylitis, aortitis is thought to occur late in the disease process and may be quite common. Generally only thickening of the aortic wall is evident; however, this may lead to aneurysm formation, thickening and retraction of the aortic or mitral valve leaflets causing regurgitation, and/or fibrosis of the upper septum leading to conduction abnormalities. As with all largely subclinical processes, more detailed investigations lead to higher reported prevalence rates, and with transesophageal echocardiographic evaluation, root and valve abnormalities are found to be more than threefold more common in patients with ankylosing spondylitis than in control populations.⁶³

Scleroderma is not currently considered a major cause of valvular heart disease, but modest thickening of the leaflets with shortening of the chordae tendineae is common in echocardiographic studies, as is mild regurgitation. In the authors' experience most patients who require intervention for valve lesions have aortic stenosis, although at this time it is not evident that the prevalence exceeds that in the normal population.

PERICARDITIS

The rheumatologic condition classically associated with typical symptomatic pericarditis is lupus, with up to one fourth of patients having a syndrome of positional chest pain, fever, tachycardia, and/or pericardial rub, usually associated with an effusion.⁶⁴ Chest pain is common in lupus flares, and pericardial effusions are more common than true pericarditis. Pericarditis is rarely the dominant clinical syndrome in an index event; thus most patients seek treatment from rheumatologists rather than from a general medical or cardiac clinic. All types of pericardial involvement have been described, most commonly fibrinous pericarditis, and the pathologic basis appears to inflammatory depositions (immunoglobulin, C1q, C3) in the walls of pericardial vessels.⁹ Treatment is adequate control of lupus activity, with direct intervention rarely being required. It is remarkable how quickly even large pericardial effusions improve with corticosteroid therapy.

Pericardial effusions are also common in scleroderma, although clinical pericarditis is uncommon. Autopsy studies reveal frequent and diverse pathologic features, including fibrinous and fibrous pericarditis, adhesions, and effusions.⁶⁵ Clinically effusions are most relevant when they are associated with pulmonary hypertension, in which they provide evidence of right ventricular (RV) decompensation, and when they are associated with an active myocarditis,³³ which requires treatment in its own right.

In the setting of pulmonary hypertension, pericardial drainage should be avoided; it does not improve hemodynamics and can result in worsening of right-sided heart failure due to sudden reduction in free wall support; the apparent compression of the left ventricle that has been reported is caused by RV dominance rather than tamponade.

Clinical pericarditis is rare in RA; however, older echocardiographic and autopsy studies suggest that pericardial involvement was common before treatment with disease-modifying antirheumatic drugs was widely used. Pericardial effusions also are not uncommon in sarcoid, but clinical pericarditis is rare. Effusions tend to be inflammatory and may be regarded as an index of disease activity, often responding to steroid therapy.

Pericarditis is relatively common in Churg-Strauss syndrome (it was found in 9 of 49 patients in a recent survey)³⁹; in addition, multiple case reports highlight the association with polyarteritis nodosa, and occasional reports have indicated associations with the other large- and small-vessel vasculitides.

ARRHYTHMIAS

The arrhythmias classically associated with rheumatologic conditions are congenital heart block in lupus and heart block in sarcoid. The associations with conduction defects in scleroderma and myositis are less recognized. Atrial fibrillation, although clearly associated with RA, is underrecognized, and the prevalence of ventricular arrhythmias associated with myocarditis, impaired systolic function, and myocardial fibrosis has not been adequately delineated.

The presence of circulating autoantibodies targeting ribonuclear proteins (anti-Ro/SSA and anti-La/SSB) is associated with congenital heart block.¹²

The high mortality associated with this condition, which often requires external pacing, makes it a feared though uncommon disorder. Only around 5% of mothers with circulating antibodies will have an affected child, and although the prevalence in subsequent pregnancies is higher after a first affected child, it remains well lower than 50%.⁶⁶ In mothers at high risk of having a child with cardiac neonatal lupus, the use of hydroxychloroquine may protect against recurrence of disease in a subsequent pregnancy.⁶⁷

Lupus myocarditis has been associated with ventricular and atrial arrhythmias,⁶⁸ although no systematic study of the incidence has been undertaken given the apparent rarity of this condition; valvular heart disease, in particular mitral regurgitation, may lead to atrial fibrillation.

Granulomatous involvement and fibrosis of the atria, conducting tissue, and ventricular myocardium may lead to delayed conduction as well as atrial or ventricular arrhythmias in sarcoid.⁵⁹ Ventricular arrhythmias are thought to underlie the excess of sudden death,^{24,56} although there is a suggestion that this may be prevented with disease control using steroids.⁵⁶ When suggestive symptoms or electrocardiographic (ECG) abnormalities are present, echocardiography and troponin testing can identify patients with evidence of direct myocardial involvement who require immunosuppression and/or direct intervention for arrhythmias. The role of Holter or implantable monitoring is not firmly established but is recommended when high-grade block or ventricular arrhythmia is suspected.^{24,57}

Multiple ECG abnormalities have been reported in SSc, with equal frequency in the diffuse and limited forms. Abnormalities including septal Q waves, intraventricular conduction defects, prolongation of the PR interval, and bundle branch block are reported in over one quarter of SSc patients.¹⁸ Cases of heart block requiring pacing are thought to occur with increased frequency, and an association of SSc with myositis and sudden death,⁵³ added to evidence of myocardial fibrosis,¹⁷ leads to concerns that SSc patients may be at increased risk of ventricular tachyarrhythmias.

The association between RA and atrial fibrillation has been firmly established in the recent Danish population study,⁵ in which the incidence of atrial fibrillation was 40% higher in individuals with RA than in the general population. The incidence of stroke was 30% greater in the RA patients than in the general population. Among the proposed causes is the higher prevalence of heart failure in RA, which is strongly associated with atrial fibrillation; in addition, arterial stiffness, which is well described in RA, is also known to increase the risk of both heart failure and atrial fibrillation.

Inflammatory myopathies are associated with similar pathologic processes in the myocardium, so it is no surprise that ECG abnormalities, including various degrees of conduction delay, are commonly reported.²⁰ Pacemakers are only rarely required, and a clear association with ventricular arrhythmias, although expected (given the association with progressive ventricular impairment and sudden death), is not proven. Spondyloarthritis, in particular ankylosing spondylitis, has been clearly shown to cause heart block resulting from extension of fibrosis into the septum, but the frequency with which this occurs appears to be low, and high-grade block is rare.⁶⁹

PULMONARY HYPERTENSION

PAH is remarkably common in association with CTD. In scleroderma the estimated prevalence is approximately 10% in catheter-based studies; estimates are similar or higher in mixed CTD. In SLE the likely prevalence is under 1%, and cases are described in polymyositis and myositis.⁷⁰ An increased prevalence is suspected in sarcoid,²⁵ whereas the prevalence in rheumatoid is likely similar to background levels,⁷⁰ and in the rarer conditions there are insufficient data.

Much higher prevalences have been estimated in echocardiographic studies—due in part to the inaccuracy of echocardiographic estimations of pulmonary pressure⁷¹ and in part to the frequency of diastolic dysfunction and lung disease,^{6,15,25} which lead to elevated pulmonary pressures.

There is high prevalence of PAH in scleroderma. The DETECT study demonstrated the feasibility of screening for PAH,⁷² but only using a combination of clinical, serologic, and simple investigations, and further showed that PAH can be diagnosed much earlier in the course of the disease than previously thought possible within enriched subsets.

The second striking feature of CTD-associated PAH is the lower pulmonary vascular resistance and pulmonary pressures at the time of diagnosis compared with idiopathic PAH; this is true not just for scleroderma, but also for mixed CTD, dermatomyositis and polymyositis, sarcoid, and to a lesser extent lupus.^{25,70} It is still unclear whether this is due to greater ventriculo-arterial mismatch,⁷³ poor tolerance of rapidly escalating pressures by older patients, or the intrinsic myocardial dysfunction prevalent in CTD; the opportunity presented by early detection should help resolve this quandary. Autopsy and CMR studies suggest that myocardial involvement in SSc is

very common; and Meune and associates⁷⁴ demonstrated that although systolic dysfunction is rare—a trend toward minor diastolic abnormalities is the norm in SSc, but RV abnormalities are not particularly prevalent. Ventricular interdependence may be a way of squaring this particular circle. The left ventricle contributes to 40% of RV workload, and increasing LV contractility in isolation increases RV tolerance of afterload. It is thus possible that LV involvement in CTD is responsible for the failure of the right ventricle to tolerate higher workloads. This would explain the absence of more extensive fibrosis in the right ventricles of SSc patients than in patients with idiopathic PAH on CMR; it may also explain why the right ventricle takes a bigger hit when postcapillary pulmonary hypertension is present. If this is true, one should expect that evaluation of LV contractility in SSc-associated PAH compared with idiopathic PAH would provide insights into the lower RV tolerance of afterload.

Despite the more modest hemodynamic perturbation at diagnosis, the prognosis is worse in CTD PAH than in idiopathic PAH, except in SLE-associated PAH.⁷⁰

As a systemic condition, CTD-associated PAH requires much greater diligence in establishing the diagnosis, including being prepared to undertake left-sided heart catheterization when any doubts exist about the wedge pressure and performing a detailed assessment of coexistent lung disease. It is presently suggested that a wedge pressure of 12 mm Hg or above in an

adequately hydrated patient does not exclude postcapillary pulmonary hypertension.⁷⁵

In PAH associated with all CTDs as exemplified by SSc-related PAH, unlike in idiopathic PAH, significantly reduced gas transfer is the rule.^{70,72} This may relate to the presence of more diffuse pulmonary vascular lesions extending into the pulmonary veins.⁷⁶ It may also explain the worse prognosis associated with CTD-related PAH, because such patients tend to develop pulmonary edema on treatment with pulmonary vasodilators.⁷⁶ However, this issue is not settled. The authors' data suggest that fewer than 10% of SSc patients meet the criteria for a diagnosis of pulmonary veno-occlusive disease, and in none of the pivotal trials, or their follow-up, has an excess pulmonary edema event rate been reported in SSc patients. There is little doubt, however, that severely reduced gas transfer is indicative of a more diffuse abnormality of the gas-exchanging vasculature and a worse prognosis.⁷⁷

It may be concluded, therefore, that CTDs affect all aspects of cardiac function both directly and indirectly and that greater collaboration between cardiologists and rheumatologists would significantly improve patient care and our understanding of the cardiac contribution to adverse outcomes in these populations. The relatively low visibility of CTD in general cardiology cohorts reflects a poor signal-to-noise ratio that can be overcome with only dedicated cardiology/rheumatology clinics.

The lung in rheumatic disease

■ PAUL F. DELLARIPA ■ IVAN O. ROSAS

- All components of the respiratory system can be involved in the lung manifestations of rheumatologic disease.
- Lung disease may precede overt musculoskeletal features by several years.
- Pneumonitis caused by drugs or opportunistic infection related to immunosuppression can complicate diagnosis of lung manifestations of rheumatologic disease.
- High-resolution computed tomography with or without bronchoalveolar lavage can be helpful in differentiation of lung manifestations. Surgical biopsy may be required where there is residual doubt.
- Treatment approaches depend on the dominant pattern of disease.
- Outcome tends to be better than in the idiopathic interstitial pneumonias that share common pathologic patterns.
- Rarely, more explosive diffuse lung disease mimicking acute respiratory distress syndrome can occur. The outcome of this manifestation is often poor.
- On rare occasions, the majority if not all manifestations of an underlying autoimmune disease may be evident in the lung; this is referred to as *lung-dominant connective tissue disease*.

INTRODUCTION

Pulmonary manifestations of rheumatic diseases are among the most significant challenges for the practicing rheumatologist. Specifically, interstitial lung disease (ILD) is one of the most worrisome and challenging complications due to the progressive nature of the disease and variable response to therapy and prognosis. This chapter highlights major areas of lung involvement in specific rheumatic diseases including airway, pleural, vascular, and interstitial lung disease, the latter of which is the main focus of this chapter given its importance in rheumatologic practice.

Interstitial lung disease or parenchymal lung disease

ILD represents a significant challenge in the management of patients with rheumatic diseases. Prognosis is variable and strongly depends on the histopathologic pattern noted. Some studies suggest that ILD associated with rheumatic diseases has a better prognosis than idiopathic pulmonary fibrosis (IPF), whereas other studies suggest that prognosis is similar.¹⁻³ ILD associated with rheumatic disease occurs most commonly in scleroderma (systemic sclerosis form, or SSc), followed by polymyositis/dermatomyositis, mixed connective tissue disease, rheumatoid arthritis (RA), and less frequently Sjögren syndrome and systemic lupus erythematosus (SLE). ILD may precede the development of a specific rheumatic syndrome or present as part of a poorly defined or undifferentiated rheumatic syndrome that the rheumatologist may be asked to evaluate in the setting of active ILD.

Pathologic features in interstitial lung disease

An understanding of the histopathologic classification of ILD is important because different histologic subtypes portend different prognoses. The two

most common types of ILD associated with rheumatic diseases are nonspecific interstitial pneumonia (NSIP) and usual interstitial pneumonia (UIP), followed by lymphocytic interstitial pneumonia (LIP), cryptogenic organizing pneumonia (COP), and less frequently diffuse alveolar damage (DAD).

UIP is associated with a patchy heterogeneous process with fibrotic areas interposed with normal or near-normal lung. The distribution is predominantly subpleural and associated with honeycombing on chest computed tomography (CT) (Figs. 36.1 and 36.2). Pathologic specimens are notable for characteristic fibroblastic foci (Fig. 36.3). Although UIP is the classic pathologic lesion observed in IPF patients, it can also be seen in patients with RA, SSc, and other rheumatic syndromes. The presence of UIP in RA portends a worse prognosis than other histopathologic patterns.³

NSIP is characterized by a more uniform, homogeneous pattern, with variable degrees of inflammation (cellular NSIP) or fibrosis (fibrotic NSIP) and a noted paucity of fibroblastic foci on pathologic examination (Fig. 36.4). Typically, ground-glass opacities are noted and are often associated with a reticular pattern and traction bronchiectasis but a lack of honeycombing on chest CT scan (Fig. 36.5). NSIP is the histopathologic lung pattern seen more frequently in patients affected with rheumatic diseases and appears to have a better overall prognosis than UIP.⁴

COP, formerly known as *bronchiolitis obliterans organizing pneumonia*, is an inflammatory disease that predominately involves the distal airways (acini and respiratory bronchioles) and is characterized by its responsiveness to steroids. It is associated with many rheumatic diseases including SLE, RA, and polymyositis/dermatomyositis.

LIP is characterized by extensive lymphocytic infiltration associated with peribronchial lymphoid follicles; it is most often seen in Sjögren syndrome and RA and may be a feature of ILD in undifferentiated forms of autoimmune disease as well.

DAD is notable for the development of hyaline membranes. It can develop in a variety of rheumatic syndromes including SLE and polymyositis/dermatomyositis. DAD can occur *de novo* or in patients with preexisting lung disease. The presence of DAD is usually associated with severe respiratory failure and overall poor prognosis.

It is important to note that it is more difficult to predict progression in ILD associated with rheumatic syndromes than in IPF with its more predictable steady decline.

EVALUATION OF PATIENTS WITH LUNG INVOLVEMENT IN THE RHEUMATIC DISEASES

Radiographic studies

Chest radiography is not particularly sensitive in detecting mild forms of ILD; however, it may be useful in excluding other conditions such as congestive heart failure, pleural disease, and pneumonia. Chest CT with high-resolution imaging (HRCT) is the test of choice in detecting ILD, and detection of characteristic findings on CT may predate the onset of clinical symptoms.⁵ The most common finding in ILD is the presence of ground-glass opacities, which are characteristic of inflammatory disease and most often associated with NSIP. Another important finding is the presence of honeycombing (cystic spaces within clearly definable walls), which typically is found in a subpleural distribution and is pathognomonic for UIP. There is reasonable correlation of the radiographic appearance on chest CT with histopathologic changes in UIP and NSIP.⁶ Computer-aided quantitative scoring of CT scans is emerging as a method to detect and quantify the extent and severity of fibrosis.

Fig. 36.1 Computed tomographic scan of the chest shows the pattern associated with usual interstitial pneumonia (UIP). Note the peripheral coarse honeycomb pattern that is the hallmark of UIP.

Fig. 36.2 High-resolution computed tomographic scan of the chest shows fibrotic changes in a subpleural distribution with honeycombing consistent with usual interstitial pneumonia.

Fig. 36.3 This 40x view shows characteristic features of usual interstitial pneumonia (UIP) with the presence of normal lung (indicated by asterisk) next to fibrotic lung, which illustrates the temporal heterogeneity of UIP. Fibroblastic foci, commonly seen in UIP, are indicated by the arrows.

Fig. 36.4 This 40x view shows homogeneous inflammation and fibrosis of the interstitium of the lung characteristic of nonspecific interstitial pneumonia. (Courtesy Lynette Sholl, MD, Brigham and Women's Hospital.)

Fig. 36.5 High-resolution computed tomographic scan of the chest shows bilateral ground-glass opacities without honeycombing in a patient with dermatomyositis, which is consistent with nonspecific interstitial pneumonia.

Pulmonary function testing

ILD is characterized by the presence of restriction on spirometry and plethysmography (reduced forced vital capacity [FVC], increased ratio of forced expiratory volume in 1 second to FVC, a low total lung capacity, and low carbon monoxide diffusion capacity). The 6-minute walk test is a useful and simple test that can suggest early interstitial or pulmonary vascular disease when oxygen saturation drops below 95%; however, the use of the 6-minute walk test in clinical practice for this purpose has yet to be validated.⁷

Bronchoalveolar lavage

The main role of bronchoscopy, bronchoalveolar lavage, and transbronchial biopsy in ILD is to determine if there is concomitant infection. In rare instances an alternative diagnosis is established, such as granulomatous disease. Assessment of cell differentials and specific cell type predominance, such as a predominance of neutrophils, does not serve as an independent predictor of disease progression or response to treatment, as noted in the Scleroderma Lung Study.⁸

Lung biopsy

In many cases, when the disease pattern on HRCT clearly favors one diagnosis and the clinical features are straightforward, lung biopsy may not be necessary or advisable. However, when the clinical presentation is atypical or poorly differentiated or when other diagnoses such as COP or infection are being entertained, lung biopsy may offer important information that can influence treatment decisions.

Systemic sclerosis

Pulmonary disease is the leading cause of mortality and morbidity in SSc. Although ILD is the most common pulmonary manifestation, other complications such as aspiration pneumonia and pulmonary hypertension can occur separately or concomitantly with ILD.

The prevalence of disease varies from 25% to 90% depending on the subtype and definition of scleroderma, although clinically significant ILD in scleroderma occurs in about 40% to 50% of patients with diffuse disease and in about 30% of patients with limited disease.⁹ Most of the morbidity and progression of ILD in diffuse SSc occurs in the first 4 to 5 years, and severe ILD can occur in patients with limited disease and also in patients without cutaneous involvement of scleroderma, known as *sine scleroderma*.¹⁰ The predominant pathologic pattern seen is fibrotic NSIP followed by UIP; rarely COP and DAD may be seen.^{3,11} The pathogenesis of the fibrosis is not fully understood, but transforming growth factor- β , platelet-derived growth factor, and endothelin-1 among other cytokines, chemokines, and mediators play an important role in disease progression.¹²

Two prospective clinical trials using cyclophosphamide showed very modest benefit in terms of survival or clinically significant improvement in pulmonary function based on HRCT or pulmonary function tests (PFTs). In the Scleroderma Lung Study, oral cyclophosphamide was administered for a duration of 1 year, and a small improvement in FVC was noted after 1 year, although this benefit was not maintained by the end of year 2.¹³ In another prospective trial, a trend toward improvement in FVC was noted in patients given intravenous cyclophosphamide 600 mg/m² monthly for

6 months with prednisone 20 mg administered on alternate days followed by azathioprine for an additional 6 months.¹⁴ On balance, although the benefits of cyclophosphamide in scleroderma are modest and the benefits must be weighed against the risk of significant toxicity, cyclophosphamide may be useful in patients with ILD and is recommended as a treatment option by the European League against Rheumatism. Novel approaches for the treatment of ILD associated with scleroderma include tyrosine kinase inhibitors, mycophenolate mofetil, endothelin antagonists, and a host of emerging molecules that affect fibroblast proliferation.¹⁵

Aspiration related to esophageal dysmotility is seen commonly in SSc and may play a role in either the pathogenesis or exacerbation of ILD in SSc.¹⁶ Although no prospective trials have measured progression of lung function in response to control of reflux, it may be beneficial to minimize the risk of reflux by using high-dose proton pump inhibitors or to consider antireflux surgery in patients with evident ILD.

In some patients, severe pulmonary hypertension and ILD can occur concurrently, which is among the most challenging scenarios in terms of prognosis and therapy. Early recognition is important given the now numerous therapeutic options available to treat pulmonary hypertension, which may enhance survival and quality of life.

In summary, the initial pulmonary assessment of all patients with scleroderma involves baseline pulmonary function testing, HRCT, and echocardiography. Assessment using an algorithm combining findings on pulmonary function tests and HRCT can aid in prognostication and decisions regarding treatment.¹⁷ If significant ILD is present that appears to be progressive, then a trial of cytotoxic or other immune-modulating therapy with or without steroids may be considered, although data supporting their benefit is limited based on clinical trials in scleroderma patients. Finally, there are several ongoing trials assessing the use of stem cell transplantation in patients with aggressive disease, and patients with rapidly progressive lung disease may be considered for lung transplantation in selected centers.

Rheumatoid arthritis

Pulmonary disease is relatively common in RA. Although morbidity is more readily apparent in the articular system, increased mortality, observed in the first decade, can be attributed mostly to extraarticular organ involvement, in particular involvement of the cardiopulmonary system.^{3,18} A history of smoking (past or present) is a strong predictor of extraarticular organ involvement.¹⁹

The most significant pulmonary complication is RA-associated interstitial lung disease (RA-ILD), which occurs in nearly 10% of the RA population based on national data.²⁰ The histopathologic patterns most commonly seen are UIP and NSIP. Most interstitial pneumonias associated with collagen vascular disease have a slower rate of progression and better prognosis than idiopathic interstitial pneumonias (i.e., IPF) independent of histopathologic classification; however, RA-ILD with a UIP pattern has a worse prognosis than that with an NSIP pattern.^{3,21} Interestingly, histologic findings of UIP in lung biopsy specimens of patients with RA-ILD may be more frequent in smokers than in nonsmokers.²² The significance of anti-cyclic citrullinated peptide antibodies and citrullination in patients with RA-associated ILD and in patients with ILD without clinically evident RA is uncertain.²³

The incidence of RA-ILD has a bimodal distribution with a majority of patients developing ILD a decade after the onset of articular manifestations and a minority of patients developing clinically apparent disease shortly after the development of articular disease.²⁴ In a small subset of patients lung involvement is the first disease manifestation of RA. In general, RA-ILD with this atypical presentation is similar in clinical course, response to treatment, and prognosis to other RA-ILD.²⁵ These diverse clinical phenotypes suggest that genetic factors and environmental determinants (e.g., smoking) are potential disease modifiers that influence outcomes.

Preclinical ILD is relatively common in RA, and studies in which open lung biopsy or chest CT was performed demonstrate lung involvement in more than 40% of the study population.^{26,27} In one study, 33% of RA patients without dyspnea or cough had ILD as identified by chest CT scans; preclinical ILD like RA-ILD was associated with a history of smoking (past or present). Importantly, disease progression has been observed in this type of patient, which suggests that clinically significant pulmonary fibrosis is likely to develop in a subset of patients affected with preclinical RA-ILD.²⁴

Bronchiectasis or bronchiolectasis is observed in up to 30% of patients with RA studied with chest CT.²⁸ Similarly, obliterative bronchiolitis is more common in RA than in other rheumatologic diseases. Although the prevalence of obliterative bronchiolitis is low, the prognosis is poor due to the lack of effective treatments, and lung transplantation may be required to prolong survival and improve quality of life. Other forms of bronchiolar involvement may show an obstructive clinical picture and mosaicism on CT

scan similar to that seen in obliterative bronchiolitis but have a better overall prognosis and may be amenable to immunomodulating therapy.

Pulmonary nodules are usually an incidental finding on chest CT or, less frequently, open lung biopsy.²⁹ Nodule cavitation may result in hemoptysis or pneumothorax through the rupture of subpleural nodules. Caplan syndrome consists of nodules associated with coal miner's pneumoconiosis. Pleural disease is common in RA, and pleuritic pain occurs at some time in at least 20% of patients.

Dermatomyositis/polymyositis

The idiopathic inflammatory myopathies are a group of disorders characterized primarily by immune-mediated destruction and dysfunction of muscle; however, the disease frequently involves the skin, joints, cardiopulmonary system and lung, in the latter instance manifesting most notably as ILD. In some cases, rapidly progressive ILD may develop in patients with amyopathic dermatomyositis, and prognosis may correlate with the presence of anti-CADM-140/MDA5 antibody.³⁰ The most common variant of connective tissue disease-associated ILD is antisynthetase syndrome in which antibodies directed against Jo-1 (histidyl-transfer RNA [tRNA] synthetase) and other amino-acyl tRNA synthetases such as PL-12, PL-7, and others are associated with a clinical syndrome characterized by myositis, fever, Raynaud phenomenon, mechanic's hands, arthritis, and ILD.³¹

Although estimates of the overall incidence of ILD associated with inflammatory myopathy range from 5% to 45%, lung involvement is clearly more prevalent among patients possessing antisynthetase antibodies.³² Case series which included pathologic analysis have shown that ILD associated with antisynthetase syndrome encompasses a variety of histopathologic subtypes, including NSIP, COP, UIP, and DAD.^{33,34} As expected, response to therapy and overall prognosis largely reflect the underlying lung histologic characteristics. The predominance of NSIP in the majority of myositis-associated ILD case series may explain increased survival rates compared with more common idiopathic interstitial pneumonias like IPF.^{31,35}

Contrary to these data, recent evidence suggests that there is a subset of anti-Jo-1 antibody-positive individuals who have a rapidly progressive form of ILD that is reminiscent of the acute disease exacerbations observed in IPF patients.³⁶ Antiinflammatory and immunosuppressive therapy is likely to fail in these patients because of rapid disease progression, and therefore patients who are otherwise eligible should be referred early for lung transplant evaluation.

Systemic lupus erythematosus

Chest wall pain, costochondral pain, and pleurisy are common in SLE and often are part of the initial presenting symptoms, and clinically it may be difficult to distinguish between musculoskeletal and pleuritic pain. Pleurisy occurs in up to 50% of patients with SLE, but only a small percentage actually develop effusions, which typically are exudative with modestly low glucose concentration and complement levels.³⁷ Treatment is administered to symptomatic patients only and includes nonsteroidal antiinflammatory drugs (NSAIDs) in mild cases and corticosteroids in more severe cases.

Acute pneumonitis is a rare, poorly understood, but feared complication of SLE. It is characterized by fever, cough, dyspnea, and progressive hypoxemia. Sometimes, hemoptysis may be noted and chest radiographs show diffuse infiltrates and pleural effusions. Chest CT scans may show ground-glass opacities and consolidation. Biopsy specimens may show DAD with or without alveolar hemorrhage and capillaritis. The mortality associated with this syndrome is high, reported as 50% in one study of 12 patients.³⁸ Treatment includes high-dose steroids and consideration of additional immunosuppressive agents such as cyclophosphamide, although no controlled trials exist to guide therapy. In rare cases a more chronic ILD may develop in SLE, which may or may not occur following an acute pulmonary condition, and treatment considerations are similar to those noted earlier for ILD related to scleroderma.

Diffuse alveolar hemorrhage can occur in up to 4% of patients with SLE. It typically is found in a patient with known SLE who has dyspnea, cough, and often hemoptysis, although some patients have anemia and bilateral infiltrates without hemoptysis. In patients known to have SLE, one must consider underlying infection, pulmonary embolism, and capillaritis. Biopsy specimens may reveal bland hemorrhage, immune complex deposition, or capillaritis. Distinguishing this syndrome from acute pneumonitis can be difficult. Mortality can be high, and treatment involves the use of steroids, cyclophosphamide, and in some cases plasmapheresis.³⁹

Acute reversible hypoxemia can occur in patients with SLE who have unexplained hypoxemia and normal chest radiographs. Treatment with corticosteroids and aspirin can be effective.⁴⁰ Shrinking lung syndrome has

been noted in SLE and is characterized by dyspnea, pleuritic pain, and progressive decrease in lung volume. The syndrome should be considered in those patients with SLE who have dyspnea, clear chest radiographs, and elevated diaphragms. Pulmonary function tests may show an abnormal diffusion capacity that corrects for alveolar volume, and esophageal manometry may be useful to identify an abnormality in lung compliance. Corticosteroids, theophylline, and other immunosuppressive agents as well as pain control may be beneficial, although generally the disorder is self-limiting.⁴¹

Pulmonary hypertension occurs in a small but significant portion of patients with SLE. Mild to moderate disease may occur in up to 40% of patients.⁴² Recurrent thromboemboli also can result in pulmonary hypertension, especially in those with antiphospholipid antibody syndrome. Treatment of pulmonary hypertension in SLE is similar to that described for pulmonary hypertension in scleroderma. In some cases pulmonary hypertension in SLE may be due to pulmonary vasculitis as opposed to a plexogenic vasculopathy, and cyclophosphamide and rituximab may be useful therapeutic interventions.^{43,44}

Sjögren syndrome

Sjögren syndrome may have a variety of pulmonary manifestations, including bronchial and airway narrowing, ILD, cystic changes, and lymphoproliferative disease including, in rare cases, lymphoma.

Patients with Sjögren syndrome frequently complain of a dry cough and show evidence of hyperactive airways secondary to inflammatory infiltration of bronchial submucosa. ILD includes NSIP, UIP, COP, and LIP, with NSIP noted most frequently.⁴⁵ In certain cases, the distribution of lymphocytic infiltration is more localized to the bronchial tree, a condition known as *follicular bronchiolitis*.

Nodular lymphoid hyperplasia (pseudolymphoma) also may occur in Sjögren syndrome and is characterized by pulmonary nodules or infiltrates containing reactive lymphoid cells. On CT such lesions may be difficult to distinguish from B-cell lymphoma of the extranodal marginal zone B-cell type or more aggressive forms of non-Hodgkin lymphoma, and thus biopsy may be required.⁴⁶ Treatment options for ILD in Sjögren syndrome are similar to those for other forms of ILD and may also include B cell–deleting agents.

Drug-induced lung injury

A host of medications used in rheumatologic practice have been implicated in lung injury, most notably methotrexate (MTX). MTX lung toxicity usually presents within the first 1 to 2 years of treatment with the drug, and clinical manifestations can range from a cough to fulminant presentations with fever, progressive dyspnea, and life-threatening respiratory failure. Radiographs and CT scans may show diffuse or focal infiltrates, and pathologic findings include prominent lymphocytic infiltration, acute interstitial pneumonia, and sometimes COP. Although a chronic fibrotic lung reaction to MTX has been implicated, there is no clear evidence to support this interpretation, and many cases labeled as chronic MTX fibrotic disease probably represent progression of underlying ILD in patients with RA. Risk factors for MTX lung disease include older age, diabetes, hypoalbuminemia, and perhaps previous lung disease.⁴⁷ In patients with minimal underlying lung disease it is reasonable to consider using MTX, although with careful observation and monitoring.

Pneumonitis may occur in up to 1% of patients receiving leflunomide, and it may be more common in patients previously treated with methotrexate.⁴⁸ Other agents used in rheumatologic practice that may result in pulmonary toxicity include azathioprine, sulfasalazine, minocycline, NSAIDs, D-penicillamine, gold, and cyclophosphamide, rituximab, and adalimumab. In all cases of suspected drug-induced lung toxicity, treatment involves cessation of therapy in mild cases, consideration of underlying infection using bronchoscopy, bronchoalveolar lavage if needed, and use of corticosteroids in more severe cases.

The use of tumor necrosis factor (TNF)–modulating agents in patients with RA who have ILD is a matter of significant controversy. A number of case reports have noted progression of underlying ILD in patients given TNF inhibitors (mostly infliximab), and there have also been contrary reports

that ILD has either remained stable or actually improved in patients given TNF inhibitors, but comparison of a large cohort of RA-ILD patients receiving anti-TNF therapy with those receiving traditional disease-modifying antirheumatic drugs shows no difference in mortality.^{49–51} RA patients also may have a higher risk of bronchiectasis and in more severe cases are at higher risk of infectious complications. Therefore in RA patients with significant ILD or bronchiectasis, caution should be exercised in the use of TNF inhibitors.

Lung and vasculitic syndromes

Diffuse alveolar hemorrhage as a result of capillaritis is an important feature of various vasculitic syndromes, including antineutrophil cytoplasmic antibody (ANCA)–associated granulomatous vasculitis, microscopic polyangiitis, Goodpasture syndrome, SLE, and, in RA, rarely cryoglobulinemia and antiphospholipid antibody syndrome.⁵² Capillaritis may manifest clinically with hemoptysis, although there may be no clinical evidence of bleeding even on bronchoscopy. Capillaritis should be suspected in patients with respiratory symptoms, falling hematocrit, radiographic abnormalities including diffuse lung infiltrates and ground-glass opacities, and elevated diffusion capacity as the main clues to active bleeding in the lung. Lung biopsy may be helpful to distinguish pauci-immune disease associated with ANCA from immune complex– and complement-mediated diseases seen in SLE or anti-glomerular basement membrane disease seen in Goodpasture syndrome, although tissue is often more accessible from the kidney or other sources with less morbidity. Fibrosis and airflow obstruction as a result of chronic inflammation have been noted in ANCA-associated lung disease.^{53,54} Treatment involves administration of high-dose corticosteroids, cyclophosphamide, rituximab, or other immunomodulating agents and consideration in severe cases of plasmapheresis, especially in Goodpasture syndrome, although its usefulness in ANCA-associated pulmonary hemorrhage syndromes is uncertain.

TREATMENT OF INTERSTITIAL LUNG DISEASE ASSOCIATED WITH THE RHEUMATIC DISEASES

Except for ILD in scleroderma, there are no prospective, randomized trials examining the treatment of ILD in the rheumatic diseases. Therapeutic choices for ILD associated with the rheumatic diseases have therefore been extrapolated from the scleroderma experience, which may not be appropriate given the varied histopathologic patterns and natural history of lung disease in the different rheumatic disorders. In patients with active clinical symptoms and evidence of inflammatory disease or a mix of inflammatory and fibrotic disease on CT scans and/or cellular NSIP on lung biopsy specimens, a trial of antiinflammatory therapy with high-dose steroids and a second agent such as cyclophosphamide, mycophenolate mofetil, azathioprine, or a calcineurin inhibitor is a reasonable option. In severe disease, a 6- to 12-month course of cyclophosphamide followed by transition to a second agent such as mycophenolate mofetil or azathioprine is a reasonable clinical approach. In patients with predominantly fibrotic ILD, no clear therapeutic regimen can be recommended, although agents such as mycophenolate mofetil, pirfenidone, N-acetylcysteine, or other emerging agents that may have antifibrotic effects may prove beneficial.^{15,55–57} Emerging T and B cell–based and anticytokine therapies (e.g., those used in RA) may have a beneficial effect on coexisting lung disease. In patients who are treated, prophylaxis for *Pneumocystis jiroveci* pneumonia should be strongly considered, and immunization against influenza and pneumococcal pneumonia is strongly recommended. Finally, early referral for lung transplant evaluation should be considered in patients with progressive disease or poor response to therapy and good performance status.

In summary, great challenges still exist in our understanding of the natural history and treatment of ILD and other pulmonary manifestations in the rheumatic diseases. Expertise in capillary microscopy, elicitation of subtle clues on clinical examination, and interpretation of sophisticated immunologic testing are of great importance in establishing the appropriate diagnosis and tailoring treatment. Working in close collaboration with pulmonologists, radiologists, and pathologists, rheumatologists have much to offer to this most challenging group of patients.
